Compared to Dight's sample, a smaller proportion of male patients and a larger proportion of male nurses were regular drinkers. Non-drinkers were more common among male patients than among male nurses or Dight's sample. There were similar proportions of regular drinkers and non-drinkers among females in their 20s in all three groups. Of females in their 30s, however, a smaller proportion of patients and a larger proportion of nurses were regular drinkers than in Dight's sample; while non-drinkers were more common among female patients than among nurses or Dight's sample.

This study thus confirms the finding of Samarasinghe *et al* (1984) that most patients referred to nurse therapists for behaviour therapy drink less, not more, than the general population, and that they do not in general find alcohol or sedative drugs reliable as anxiolytics. Few fit the picture (Quitkin *et al*, 1972) of anxious people pursuing anxiolytic effect to the point of dependence. Those few raise important case management and theoretical issues.

Case management

In following the case management guidelines suggested by Samarasinghe *et al* (1984) the author asked four (10%) of the Dumfries patients to stop or reduce use of alcohol or drugs prior to behavioural treatment: the two agoraphobics; a social phobic who regularly drank heavily to allay anxiety; and an obsessional who used 10 mg lorazepam per day and feared worse symptoms if she stopped. The social phobic complied. The obsessional refused to reduce her drugs but agreed to refrain from use before treatment sessions. The two agoraphobics felt unable to comply with the request that they reduce drinking or at least agree to abstain before treatment and homework sessions, despite compliance being a precondition of treatment. The issue of dependence was then discussed and referral for help with this, with the prospect of later re-assessment, was offered. Neither was subsequently re-referred for behavioural treatment.

Thus two (5%) of the patients did not enter behavioural treatment for their anxiety-related problems when these guidelines were followed. The application of these guidelines could be construed as successful. A few problems of dependence were highlighted, though the most severe were already known and had been the focus of at least partially unsuccessful treatment. A few patients modified their use of these substances in ways that literature on anxiety-'fuelling', state dependent learning and attribution (Sartory, 1983; Stockwell *et al*, 1984) suggests may be helpful. Difficulties of trying to implement behavioural treatment with patients experiencing problems of dependence were, perhaps, avoided. The uncertainty on this point is important. The arguments of the above studies, though well-founded theoretically, have yet to be conclusively validated in the clinical setting. Following these management guidelines precludes, for example, single case studies of behaviour therapy given during periods of alcohol or sedative use and abstention, which might further understanding of the relationship of substance use and treatment efficacy. Two questions are thus raised: (a) given the current state of knowledge are therapists justified in requiring patients who are not asking for help with their use of alcohol or sedatives to change it in order to have behaviour therapy? and (b) if heavy users of these substances are screened from behaviour therapy, how can the claim that such use works to the detriment of that therapy be refuted?

Finally, while the emphasis of this paper has been on alcohol and sedative use, the high proportion of smokers among the anxious patients should be noted. Further study and consideration of appropriate intervention is needed.

Acknowledgements

I would like to thank Ron McKechnie and Dr D. Samarasinghe for help and advice.

Point of View

Brief Psychoses: Do They Contribute to the Good Prognosis and Equal Prevalence of Schizophrenia in Developing Countries?

JANICE STEVENS

A high incidence of brief schizophrenia-like psychosis in Africa and other parts of the developing world has been repeatedly documented by many psychiatrists working in these regions (Dembovitz, 1945; Carothers, 1953; Jilek & Jilek-Aall, 1970; German, 1972; Leighton *et al*, 1963). This report does not deny that typical schizophrenia occurs in these countries, but the common culturally based schizophrenia-like psychosis may be misdiagnosed as schizophrenia, and thus inflate prevalence and improve prognosis data.

Most prevalence and outcome studies of schizophrenia in developing countries are based on individuals who are brought to out-patient clinics and hospitals. Although the number of these patients cannot be the basis for establishing prevalence throughout a region, it is possible to examine and compare clinical phenomenology and patient mix with similar data from Europe or North America, recognising that in general, only those with the most severe illnesses or who live reasonably close to the facility are likely to come to the hospital or clinic in less developed countries. Such a survey was undertaken by the author during a three-month tour in 1984 as Visiting Senior Lecturer in Psychiatry at the Medical School of the University of Zimbabwe.

The distribution of psychiatric diagnoses entering the mental hospitals in Zimbabwe is both similar to and different from that in the USA and Europe. In Harare, Zimbabwe's largest city, 40–50% of all admissions were diagnosed schizophrenia in 1983–1984. However, if Research Diagnostic Criteria (Spitzer & Endicott, 1978), requiring at least two weeks of illness for diagnosis of schizophrenia, are applied, more than half of these patients fail to meet the duration criterion. Instead, the condition would be diagnosed brief reactive psychosis. If the six months of continuous illness required by DSM-III (American Psychiatric Association, 1980) for diagnosis of schizophrenia is used, only 10–15% of admissions meet the criteria. Only 5–6% of admissions were diagnosed affective disorders, nearly all of manic type with no history of depressive episodes. Ten percent were diagnosed alcohol-related psychoses, 5–8% puerperal and the remainder accounted for by a variety of organic brain syndromes, including pellagra, severe anaemia, general paresis, cerebral malaria and alcoholic psychosis. Notable by their rarity or absence were the senile and presenile psychoses, major depressive psychoses, and eating disorders. Common were two syndromes that are relatively unusual causes of hospital admission in North America and Europe, namely brief reactive psychoses and psychoses of essentially similar form attributed to cannabis.

This report does not attempt to review the abundant literature on phenomenology of psychiatric illness of Africa or other developing areas, but is focused on the questions of the contribution of acute schizophreniform psychoses to prevalence and prognosis data. These are questions of great importance for those concerned with the aetiology and thus the epidemiology of schizophrenia.

Brief reactive psychoses

Frequency of acute psychoses as a cause of admission to hospital has been reported by a number of psychiatrists working in Africa and in other areas of the developing world (Bert, 1951; Gelfand, 1956; Collomb, 1967; Lambo, 1965). The acute brief psychoses occur in otherwise healthy young men and women of any age, but predominantly in young adults. They are characterised by relatively abrupt onset of extreme restlessness, insomnia, mental confusion, auditory and visual hallucinations, delusions of being controlled by others, incoherent rambling, pressured speech, disrobing, destructive and combative behaviour such as tearing or burning clothes, destroying property, and attacking or beating relatives. In Zimbabwe, patients so afflicted nearly always have a strong belief in supernatural forces controlling their lives and in the power of the traditional healer (*n'anga*) to control these forces. Often, a trip to the traditional healer for explanation of some untoward event directly preceded onset of the psychosis. Prior to use of electroconvulsive treatment and neuroleptics, these psychoses lasted 1–4 weeks (Dembovitz, 1945). With modern treatment, the course is generally half this length.

With or without treatment, recovery is usually complete.

Case histories

Case 1

A young teacher was brought to the psychiatric hospital by the police after smashing several plate-glass windows in local shops and breaking the windows of cars parked on the street. He then took off all his clothes and walked or ran nearly 10 km through the town stark naked. When captured, he was intensely aggressive, talked incoherently and claimed voices were talking to him and directing his actions. Following recovery, which required several weeks of treatment with high dose, high potency neuroleptics, he told the following story.

Approximately one month prior to onset of his running amok, he consulted a local *n'anga* to determine whether the future of his job was secure. The *n'anga* told him his workmates were jealous of him and might try to harm him. A few weeks later he found a 'flash card' in his office. It read, 'To die'. He knew at once that his colleagues planned to murder him, probably by bewitchment. This episode would not leave his mind. Hallucinated voices began to echo his thoughts; and his state of wild excitement ensued. He also admitted that prior to all these events he had been smoking 'dakha' (marijuana, cannabis) regularly.

Case 2

A 65-year-old widowed African woman was well until three days before admission to the psychiatric unit at Harare Hospital when she developed sleeplessness and restlessness and 'talked nonsense'. Five days before admission she had gone to the traditional healer because of headache. She was told that evil spirits had entered her head. Poultices soaked with a brew of herbs were applied to her scalp. She became increasingly restless and was brought to the hospital by police. On examination, this thin, elderly woman was found lying on the floor of the nurse's office, talking incessantly and irrelevantly, and unresponsive to commands. There were large patches of raw peeling skin on her head where the *n'anga*'s application of caustic herbal poultices had succeeded in removing her hair and scalding her scalp. She responded quickly to modest doses of chlorpromazine. When she recovered she told us that shortly before her illness she had received word that all her daughter's clothes and money had been stolen. In her view, this could not be an accident. Anxiety over the event, plus her fear of bewitchment, evidently triggered a typical brief psychosis.

Case 3

A 20-year-old unmarried woman was brought to hospital by relatives because of severe assaultive behaviour of abrupt onset. On admission she was excited, disoriented, evidently hallucinated, and combative. She was placed in isolation and treated with chlorpromazine, and recovered rapidly. Her sister then told us that the patient's father had by mistake taken her menstrual cloths to the *n'anga*, thinking they belonged to his (unwanted) second wife. The purpose of his visit was to have the *n'anga* injure this wife by charms applied to her used cloths. When the daughter discovered that the father had taken her cloths she was terrified (menstrual cloths are carefully tied up in a bag after use and no one is allowed to touch them for fear they may be used to bewitch the owner). Her typical brief psychosis ensued.

Discussion

Brought to hospital in handcuffs or tied up with rope, these patients, although initially violent, generally respond rapidly to sedation and seclusion. All symptoms usually disappear within 2–14 days. The patient typically claims amnesia for the entire period of onset and excitement. Less commonly the presentation is of extreme social withdrawal, mutism and negativism, also associated with auditory and visual hallucinations and feelings of being controlled by outside forces. In contrast to schizophrenia, which the episodes often resemble clinically, the brief psychoses are nearly always preceded by a definite environmental stress – usually a conflict arising from domestic strife, employment problems, accidents, illness or death in the family. In addition to such stressful social, economic and domestic events, prolonged or unusual physical illness in a close relative or friend is also a common reason for seeking explanations and help from the traditional healer. Thus most patients have consulted a traditional practitioner at some point proximate to their entry to hospital, and have been told either that their ancestral spirits are angry over some breach of rites, or that they have been bewitched.

We have been interested in a possible infectious origin for schizophrenia or some schizophrenias (Stevens *et al*, 1984). The better prognosis reported for schizophrenia in developing countries suggested that these brief schizophrenia-like psychoses might represent an encephalopathy that is quickly overcome by individuals with high immunity due to residence from infancy in relatively unsanitary environments. A similar proposal has been made to explain the more benign course of adult poliomyelitis and comparative rarity of multiple sclerosis in countries where sanitation is poor and both children and adults develop a high degree of immunity to many infections (Poskanzer *et al*, 1963).

To investigate whether some of these cases represented toxic psychoses, infection, or manifestations of psychomotor epilepsy, examinations were made of cerebrospinal fluid, electroencephalogram, urine screen for toxic agents, and peripheral blood smear for malaria or sleeping sickness in a number of typical cases. These studies were generally negative in the absence of a history or clinical signs of intoxication or infection. Rather than an infectious or toxic precipitant, it appeared, as also noted by Lambo (1965) and many others, that some untoward event in their lives coupled with a strong belief in and fear of easily angered spirits or bewitchment set the stage for the brief psychosis. Similar states were described in Europe at the turn of this century (Meynert, 1889) and have occurred, sometimes in epidemic proportions, among many ethnic groups undergoing cultural change.

In Zimbabwe, and elsewhere in Africa, the belief in witchcraft and fear of ancestor retribution are kept alive by the traditional healer, whose business it is to diagnose and treat all the disorders that are believed to arise from these two causes. The traditional healing sector in Zimbabwe is represented by more than 40 000 indigenous practitioners – diviners, healers, and herbalists – who are consulted by an estimated 90% of the African population. These practitioners learn their trade from an elder kinsman, or are 'called' to their profession during a dream or a state of possession. Many report that they become healers during or after experiencing a personal psychosis – itself considered evidence of spirit possession. Most diviners and healers have little or only a few years of education and many cannot read or write (Chavunduka, 1978).

The traditional healer is not only the first source of consultation for most patients with mental illness and epilepsy, but is also consulted by a majority of individuals or families when Western medicine fails to effect a rapid cure for a variety of ailments. Even when Western treatment is successful in relieving symptoms, it seldom explains remote causality, and it is this aspect of disease or misfortune that most interests the affected individuals or their families. For it is the traditional healer and not the Western doctor who can answer the patient's and family's all-important questions: '*Why* did this happen to *me*?' and '*Who* is doing it?' With their generally frightening answers to these questions, traditional practitioners appear to play an important role in maintaining the mental set of anxiety and fear of the supernatural that underlies symptoms of the brief psychoses.

In a recent study of 100 consecutive consultations by traditional practitioners in Harare and adjoining townships, Mavi *et al* (1983) reported that 29% had gynaecological, sexual, fertility, or VD problems, 8% had diarrhoea and/or vomiting, 8% were diagnosed 'depressed fontanelle' (a widely recognised result of bewitchment in infants), seven patients had swollen limbs or stomach, five were brought for 'madness', three for epilepsy, and most of the remainder with a variety of other physical ailments. Nine came for help because of recent bad luck or misfortune. Both cause and treatment were discovered by divination. There was little relationship between the complaint, the diagnosis of cause, and the treatment. Each case was judged according to context and no general rules or principles emerged. In the 100 cited cases, bewitchment was designated as cause of the problem in 19 cases, offended ancestral spirits in 16, and possession (by evil spirits) in 11. A majority (nearly 70%) were given herbal medicines to drink, inhale or rub on the skin; a quarter were required to perform some ceremony or pay a recompense of cows, cloth or cash to offended individuals or spirits. Charms to prevent further damage were sold to ten clients.

But the traditional healer is much more than a medicine man. He or she is the principal means of communication between the living and their dead ancestors. In most African religions, it is the ancestors who alone can protect the living from all the forms of ill luck that surround their lives. Witchcraft or sorcery, the only other traditionally recognised source of misfortune, can also be detected and counteracted only by the traditional healer. As the principal arbiter between the material and spirit world, the *n'anga* is in a position not only to both arouse and dispel fears but also to foster and perpetuate a thinking style that projects the cause of both good and evil events on mystical forces external to the self. Paranoid and violent manifestations of illness are therefore common, while melancholy, self-blame and guilt are rare – perhaps because the causal agent remains externalised and blame is directed outward rather than internalised (Field, 1960; Murphy *et al*, 1967; Jilek & Jilek-Aall, 1970; Schiefflein, 1982). Belief that the locus of control for one's fate resides in outside forces that can only be discovered and dispelled by the traditional healer has important implications for understanding thought patterns of the society at large as well as for analysis of the psychoses.

The International Pilot Study of Schizophrenia (IPSS) (World Health Organization, 1979) reported in 1979 that 36% of patients in Ibadan and 27% in Agra recovered from their psychosis in less than a month. The IPSS used the Present State Examination and CATEGO program (Wing *et al*, 1974) to establish diagnoses. This diagnostic system does not include duration-of-illness criteria but relies exclusively on the cross-sectional clinical picture. Since many patients with brief psychoses meet CATEGO criteria for schizophrenia, it is likely that a proportion of the individuals diagnosed as having schizophrenia would be classified as a brief reactive psychosis, schizophreniform disorder, or atypical psychosis under the six-month time criterion set by

DSM-III. These diagnoses have a better prognosis than DSM-III schizophrenia (Coryell & Tsuang, 1986). Inclusion of brief or schizophreniform psychoses in a study examining recovery rates in schizophrenia will generate a more favourable prognosis where these are common than is the case in countries where brief and schizophreniform psychoses are less frequently seen.

Although the prevalence of schizophrenia is often stated to be similar worldwide (Sartorius *et al*, 1986), prevalence as well as prognosis in developing countries may be greatly influenced by the inclusion of brief schizophreniform psychoses in the schizophrenias. A number of investigators have reported lower prevalence rates for schizophrenia in several developing countries (Fortes & Mayer, 1969; Torrey, 1980; Dale, 1981; Torrey *et al*, 1984; Halldin *et al*, 1984; Sikanerty & Eaton, 1984). Before definitive conclusions can be drawn, however, there is a need for prevalence studies based on modern criteria, including duration and house-to-house surveys rather than clinic or hospital-based statistics.

Acknowledgements

Grateful acknowledgement is given for the assistance of many colleagues, as well as the traditional healers who permitted me to visit, photograph and tape their work.

Brief Reports

A Case of Gilles de la Tourette's Syndrome in Saudi Arabia

An occurrence of Gilles de la Tourette's syndrome in a 13-year-old Saudi female patient is documented, and treatment is described. It is thought that the improvement noted may be attributed to the hospital environment and reduced contact with the family.

Gilles de la Tourette's syndrome (GTS) is a condition that begins in childhood and is characterised by multiple motor tics and compulsive utterances that may progress to shouting of obscenities (coprolalia) (Fernando, 1976).

To the author's knowledge, no cases of the syndrome have been reported before from the Middle East: the following case report documents an occurrence, notes some cultural factors and describes the treatment of a patient in Saudi Arabia.

Case report

A 13-year-old Saudi female patient presented to the Psychiatric out-patient clinic at Riyadh Armed Forces Hospital (RAFH) with symptoms of compulsive uttering of obscenities, facial tics (blinking), other body tics and spitting. Her condition started seven years previously when she became extremely frightened one night by a group of cockroaches in a dark toilet. She spent the night crying, her sleep was restless and later she started to avoid going to the toilet to the extent of urinating and defaecating on herself. Four days later she exhibited facial tics which then progressed to multiple tics of neck, shoulders and hands. This was followed by utterances that later developed into true obscenities with a sexual or swearing content. The obscenities were reported by the patient's parents to be compulsive and worse in the presence of others.

The patient was brought up by very religious parents, and was the fourth youngest of 12 siblings. All family members rebuked her behaviour, and moreover her two older brothers were physically violent towards her. Her schoolmates used to laugh at her, calling her a "lizard". The teachers punished the patient because of her obscenities by making her stand facing the class. She was frightened to the extent of being incontinent in front of the class, and eventually she was expelled from school due to her obscene speech. Her family confined her to home, and did not allow her to talk to or play with her friends; hence she became almost isolated.

She had received treatment twice as an in-patient in two different psychiatric hospitals, but with little success. She was prescribed haloperidol: this only helped the compulsive utterances to some extent, and there were severe extra-pyramidal side-effects.

Following the initial assessment at RAFH Psychiatric Out-patient Clinic, the patient was admitted to the Psychiatric Unit of the hospital for a period of three months. During the first three weeks she received no medication, but exploratory psychotherapeutic sessions and regular meetings with the family were arranged to identify the psychodynamics and the factors of family pathology behind the condition. Physical examination and routine investigations were carried out, and showed the patient to be in good physical health, with no abnormality detected. Her IQ was found to be 'above average'. During this assessment period her behaviour was observed by our nursing staff and occupational therapist. Five forms of behaviour were identified, facial tics being the severest symptom encountered, followed respectively by utterances and obscenities; tics of neck and shoulder; spitting; and compulsive touching of the floor. All symptoms stopped completely during sleep.

At the end of the assessment period the following treatment strategy was formulated. Firstly, haloperidol was given. On a dose of 1 mg daily the patient developed severe extra-pyramidal side-effects; the dose was reduced to 0.5 mg daily, as this was found to be the maximum dose tolerated by her. Secondly, the psychotherapeutic sessions were continued, in an attempt to promote personality maturation, and so were the family meetings, in which counselling was the main theme. Thirdly, the patient attended the Occupational Therapy Department, where she was involved in different activities such as cooking, sewing and swimming.

At the end of the first week following initiation of treatment, there was a dramatic improvement of the patient's condition. This improvement was maintained throughout the remainder of the admission period, except in weeks 3 and 6 after initiation of treatment, when the patient's condition tended to be worse. The response of the symptoms to treatment appeared to be in reverse order to their sequence of onset; that is, the obsessional touching, which was the last symptom to develop, disappeared first, followed by stoppage of obscenities, then decrease of tics. The facial tics were the most resistant.

Despite the improvement in the patient's condition, the family insisted on her discharge, and although they promised to bring her as a day patient they never did. An out-patient appointment was later made, but the patient did not attend and unfortunately her condition could not be followed up.

Discussion

The results of the behavioural monitoring of this case may have important implications in terms of the aetiology of GTS, which still remains uncertain (Fernando, 1976). Nevertheless, it is known that the condition can be understood in terms of organic, hereditary, developmental, emotional and mixed models (Corbett *et al*, 1969; Enoch & Trethowan, 1979). Although it is well recognised that chlorpromazine, haloperidol and pimozide drugs have a beneficial effect in the treatment of GTS (Boris, 1968; Enoch & Trethowan, 1979; Ross & Moldofsky, 1978; Shapiro *et al*, 1983; Woodrow, 1974), the early and remarkable response of our patient to haloperidol is doubtful. This is because of the small dose of haloperidol administered and the worsening of the patient's condition at weeks 3 and 6, while she was still on haloperidol. In fact, the patient's deterioration was attributed to her contact with her family during week-end leaves, which were only granted at weeks 3 and 6, and hence reflects the bad effect of the home environment. Furthermore, there was no evidence of organic dysfunction, as indicated by the patient's good physical health and normal IQ. Therefore, the patient's improvement may be explained by the effect of the hospital environment, in terms of the better understanding and reaction of staff to the patient's symptoms, and the patient's enjoyment of the occupational therapy programme.

There is evidence in the literature that a disturbed parent–child relationship underlies the psychogenesis of the syndrome (Enoch & Trethowan, 1979). In our case this is confirmed by the results of the psychotherapeutic sessions and the family meetings, that showed the patient's inability to grow up psychologically at home, and her use of the GTS symptoms to seek the attention of her parents. The parents had 12 children, and therefore found it difficult to give attention to all of them. Moreover, the parents had always been much more attentive to the male children – a cultural phenomenon – and had applied a strict religious attitude for discipline at home.

Thus the patient acted as a scapegoat for the anxieties existing within the family by becoming the object of their perfectionist demands and punitive attitudes. The family dynamics appear to have played an important role in the maintenance and severity of this patient's illness.

Sexual Aggressivity and Androgens

Male sex hormones are ascribed a great importance in the literature from the point of view of sexual activity and aggressive behaviour. Two cases of sexually motivated murder are described, committed by delinquents with low levels of testosterone in plasma: one a patient with Klinefelter's syndrome; the other a man after castration. Even a decreased level of androgens, either primary or secondary, is not an absolute prevention of sexually aggressive behaviour.

Male sex hormones are considered to have great importance for sexual activity, as well as for aggressive behaviour. For example, Ehrenkranz *et al* (1974) studied male prisoners and divided them into three groups: those with chronic aggressive behaviour; those socially dominant but not aggressive; and typical inmates who were neither physically aggressive nor socially dominant. The testosterone level in plasma of these men correlated significantly positively with the extent of their aggressiveness. Schiavi *et al* (1984), studying XYY, XXY and a control group of men, found a significantly positive relationship between plasma testosterone level and evidence of criminal conviction. A proportionate increase in testosterone has been noted when subjects have been divided into non-delinquents, delinquents without violent convictions, and delinquents with violent convictions.

Case reports

We had the opportunity to examine two men with considerably subnormal levels of androgens, who committed violent crimes.

Case 1

A 21-year-old worker strangled and six times stabbed a 23-year-old female worker whom he did not know closely, at their working place.

The father of the defendant is a driver, the mother is a worker. Birth and early childhood development were normal. He was brought up by a dominant mother in the company of an older brother. His performance at school was poor. He passed only seven years of school. He worked as an unqualified worker. So far he has no criminal record.

He has been interested in arms and knives since his early childhood, and played with them frequently. He further admitted sadomasochistic masturbation fantasies. Before the murder he used to touch unknown women in crowds, and he wrote obscene letters to women. He has not formed any partner relationship. He admitted that he felt sexual excitation while stabbing his victim. In physical examination, highly hypoplastic testes, with volume of about 2 ml, were found. Klinefelter's syndrome was thus assumed, and was verified by genetic examination (47, XXY). The gonadotropine levels of the man were high (FSH 26.3 U/l, laboratory standard 0–7; LH 26 U/l, laboratory standard 5–20), the level of testosterone was low (3.25 ng/ml, laboratory standard 3.5–9.5) and the steroid hormone binding globulin (SHBG) was normal (19.1 ng/ml, laboratory standard 9–21). The intellect of the delinquent was slightly low (IQ 86 according to the Wechsler–Bellevue test). The EEG recording was abnormal, with irritation phenomena most pronounced in both temporal regions. The results of a neurological examination were normal.

Case 2

In a lonely place in the woods, a 34-year-old worker murdered a 64-year-old woman, strangling her with a stick and stabbing her with a knife in the chest and in the genital region. As she was dying and after she was dead, he attempted sexual intercourse with her; because of insufficient erection he did not succeed.

The offender comes from a worker's family with a bad reputation. The older brother was repeatedly convicted of rioting. The defendant passed eight classes of a special school for retarded children. He was imprisoned three times.

Earlier he repeatedly dreamt that he attacked a woman, she defended herself and he overwhelmed her. Often he had ejaculation during this dream. Since the age of 17, he repeatedly made sexual attacks on unknown women. In most cases ejaculation occurred, without coitus. When 25 years old, he was caught in this criminal activity. After his imprisonment he was, at own demand and with the agreement of his mother, castrated. Since the operation, he has only exceptionally experienced sexual fantasies and erections; ejaculation has not occurred at all.

In repeated endocrinological examinations after the murder, strongly subnormal levels of testosterone in plasma were found (0.48–0.56 ng/ml, laboratory standard 3.5–9.5).

Discussion

Case 1

Delayed sexual development has been indicated in men suffering from Klinefelter's syndrome (Raboch *et al*, 1979). Androgen level has been found to be low from the beginning of adolescence (Topper *et al*, 1982). The sexual activity of these men in adulthood is usually low (Raboch *et al*, 1979). Abnormal EEG is often found (Nielsen, 1970), as well as low intellect (Swanson & Stipes, 1969). The most typical pattern of behaviour in 47, XXY men is a tendency toward generalised passivity and lack of ambition, combined with a minor proclivity to sudden outbursts of aggression or violence (Kolodny *et al*, 1979). They often have criminal anamnesis (Nielsen, 1970). Sexual deviations also occur (Bandman & Breit, 1984). Our case can be considered as a typical example of Klinefelter's syndrome. Only the fact that he committed a sexually motivated murder can be considered extraordinary.

Case 2

Castration, as a protective measure with dangerous sexual delinquents, is carried out in some countries (Bremer, 1959), but it is also criticised (Heim & Hursch, 1979). With most men it leads to pronounced decrease in sexual activity, but some retain the capacity for coitus for a long time after the operation (Bremer, 1959). With sexual deviants, castration strongly decreases their aggressivity, and only about 10% recidivism rate has been described (Freund, 1980). The present case demonstrates that in rare cases a sexual aggressive crime can be repeated after castration.

Conclusion

A decreased testosterone level, either occurring from the beginning of sexual development (Klinefelter's syndrome) or acquired in adulthood (castration), cannot be considered as an absolute measure preventing sexual aggressive behaviour. Other factors, such as psychological, social and organic pathological ones, are also important in influencing aggressive interactions.

Erotomania and Senile Dementia of Alzheimer Type

A case of erotomania in a 75-year-old female with senile dementia of Alzheimer type (SDAT) is described. This case demonstrates the presence of an elaborately systematised delusion in SDAT, and the influence of the progression of SDAT on this delusion.

Erotomania, or de Clérambault's syndrome, consists of a delusional conviction of an amorous relationship with a socially unobtainable person with whom the subject has had little personal contact (de Clérambault, 1942). The subject is usually female, and the target of her delusion is frequently unaware of her beliefs and has done nothing to encourage them. The onset is abrupt and the course chronic. The target of the delusion remains constant (Enoch & Trethowan, 1979).

Primary and secondary forms of erotomania may exist. In primary erotomania, the delusion occurs in the absence of associated psychiatric illnesses. Reports of such cases have been rare, and the existence of this form has been questioned (Ellis & Mellsop, 1985). Secondary erotomania, or erotomania in the presence of a pre-existing psychiatric illness, has been associated with schizophrenia, schizoaffective disorder (Evans *et al*, 1982), paraphrenia (Teoh, 1972), major depression (Raskin &

Sullivan, 1974), bipolar affective disorder (Remington & Book, 1984), mental retardation (Greyson & Akhtar, 1977), cortisone psychosis, psychomotor epilepsy, meningioma and alcoholism (Doust & Christie, 1978). We report a case of secondary erotomania in a woman with senile dementia of Alzheimer type (SDAT). This case clearly demonstrates a systematised erotomanic delusion occurring in the course of SDAT. The age of onset of this delusion (75 years) is intriguing, and its relationship to the severity of SDAT is of theoretical importance.

Case presentation

Ms H was a 75-year-old widowed retired white female at the time of her enrolment in a research project investigating SDAT (Berg *et al*, 1982). Educated to the twelfth grade, she had married in her twenties and had worked 27 years as a telephone operator until her retirement at age 55. She was widowed at the age of 53. Following her retirement she remained highly functional until the age of 73, when she insidiously developed progressive memory loss, apathy, inactivity, amotivation, and loss of interest in hobbies. She was diagnosed as SDAT and referred to a research project studying healthy aging and SDAT. She fulfilled the strict inclusion and exclusion research criteria for SDAT, and was rated on our five-point Clinical Dementia Rating (CDR: absent, questionable, mild, moderate, severe) as mild SDAT (Berg *et al*, 1982; Hughes *et al*, 1982).

Past medical history was unremarkable. Past psychiatric history was notable for depressive symptoms in her early forties following menopause which lasted approximately one year. These symptoms were not treated and probably did not fulfil criteria for major depression. She had never demonstrated psychotic symptoms. Physical examination was remarkable only for obesity. Neurological examination demonstrated mild bilateral cogwheel rigidity at the elbows, without other Parkinsonian signs. Appropriate laboratory tests and CT scan were unremarkable.

Ms H's erotomanic symptoms began abruptly at the age of 75, after she met a 19-year-old maintenance man sent to repair her apartment's plumbing. In the days immediately following his visit, Ms H informed her family that this man was going to marry her. She referred to him as her "boyfriend", and announced their impending marriage. Her family had previously known the young man, describing him "trustworthy and reputable". Nevertheless, they investigated his contact with their mother, and found no evidence of improper advances or misleading statements. Moreover, he was unaware of Ms H's romantic beliefs concerning him. Over the next two years, Ms H talked frequently about her boyfriend and their impending marriage. She signed letters and cheques using his last name rather than her own. She would frequently tell her daughter of alleged communications between them. For example, she told her daughter, "He said he'd be out in the field today, but would be here for supper." (Actually, the only contacts the young man had with Ms H subsequent to his repairing her plumbing were brief, polite greetings he gave her outside the apartment complex.) Occasionally, Ms H would point out the window and state, "There my boyfriend is, ploughing out yonder", though her family would look and see no-one. Whenever Ms H's family attempted to dissuade her of her delusion, she merely giggled and persisted in her false belief.

Ms H had been free of all medication during the early course of her delusion and SDAT. During the two-year period of this delusion, she was treated by her family physician with trials of nortriptyline, ritalin, B12, and ergot alkaloids, with no apparent influence on her beliefs. Antipsychotics were refused. The patient had fluctuating depressive symptoms which did not qualify as a major depression. The delusion did not fluctuate with such symptoms.

Ms H had other concurrent psychotic symptoms. These included auditory and visual hallucinations involving her parents. She also spoke to her television, believing the actors were talking to her. During this two-year period, the SDAT progressed. By the time her SDAT progressed to a CDR moderate (77 years old), she no longer talked of her "boyfriend". Since then she has become aboulic, incontinent, wheelchair-bound, without spontaneous speech and severely demented. Auditory and visual hallucinations persist, although they no longer involve the young maintenance man.

Discussion

Delusions have been reported in a variety of organic brain syndromes, including SDAT. Our research indicates that many subjects with SDAT develop delusions during the course of their illness, although systematised delusions are less common.

SDAT is associated with major degenerative and biochemical changes (Blass, 1985). This case demonstrates that a particular type of elaborate systematised delusion may be initiated by such changes. Following the onset of erotomania, other delusions and hallucinations developed. These psychotic symptoms were episodic and not systematised. They, however, persisted as the dementia became moderately severe, whereas, after two years, the systematised erotomanic delusion gradually disappeared. It may be that Ms H's intellectual processes had deteriorated to the point that they could no longer maintain a systematised delusion, though they remained capable of generating fleeting psychotic symptoms.

To the best of our knowledge this case constitutes the oldest age of onset for erotomania, and the first case of its association with SDAT in the anglophonic literature. Apparently, age is no barrier to romantic delusions.

Capgras syndrome, de Clérambault's syndrome, and *folie à deux*

A woman with Capgras and de Clérambault's syndromes transmitted persecutory, erotic, and somatic delusions to her son in a *folie à deux*. Capgras and de Clérambault's syndromes appear together more commonly than is apparent in the literature. Review of these cases shows a strong association with severe affective disorder.

The Capgras and de Clérambault syndromes have found their way into the literature with every conceivable variant, and their occurrence together in the presence of a shared paranoid disorder (*folie à deux*) is unusual. The Capgras syndrome was elaborated in 1923 by Capgras and Réboul-Lachaux as *'l'illusion des sosies'*, the belief that persons close to the subject have been replaced by identical doubles (Enoch & Trethowan, 1979). In de Clérambault's paradigm of erotomania, the patient has the "conviction of being in amourous communication with a person of much higher rank, who has been the first to fall in love and was the first to make advances". There are many extrapolations from this 'fundamental postulate'. De Clérambault attempted to separate this syndrome from other erotic paranoid states, but not all of his own cases clearly illustrated this (Enoch & Trethowan, 1979), and the paradigm has been established solely on its content, without regard to course of phenomenology. Many cases show the presence of a severe affective disorder.

Folie à deux, although described by others, was named by La Sègue and Falret in 1877 (Enoch & Trethowan, 1979). Special circumstances permit an active or primary agent to create a delusion and gradually impose it on an associate(s), who modifies and integrates the material. The individuals live a close-knit existence, isolated from outside influences, and the delusion is more readily accepted when it is kept within the limits of possibility. Virtually any theme or category of delusion can be found, including persecutory, grandiose, religious, depressive and somatic as well as erotic. Dewhurst & Todd (1956) set out three criteria for the diagnosis of *folie à deux*: positive evidence that the partners have been intimately associated; a high degree of similarity in the general motif and delusional content; and the presence of unequivocal evidence that the partners accept, support and share each other's delusional ideas.

Case report

Mrs A, a 39-year-old, unemployed, university-educated woman, was born in a displaced persons' camp and migrated to Canada in 1953. Several operations corrected a moderate scoliosis diagnosed at nine years. Although a loner most of her life, the patient married at 22 and her only son, B, was born in 1973. She felt the marriage functioned poorly, as her husband promoted her 'bouts of jealousy' by making passes at other women.

While she may have been psychotic the year of her son's birth, psychiatric admissions began two years later. Treatment with lithium, fluphenazine and antidepressants was initiated, but she was non-compliant. In late 1981 she was admitted to hospial with grandiose, erotic, and somatic delusions (the somatic delusions concerning body odour, irritants forcing her to shave her head, unusual ideas about her corrected scoliosis, leg, and clitoris). Her agitation remitted rapidly but the delusions were unaffected by neuroleptics.

B's poor school attendance was the reason for the current presentation. Mrs A changed his school because of perceived rumours of her sexual misconduct. She sought treatment for him for numerous ailments, using the appointments to keep him out of school. Many of these are conditions from which she suffers. It was impossible to determine whether any particular physical symptom originated in Mrs A or her son.

Mrs A calls him Darwin, or some Russianised variant so that others will not know his identity; B has himself taken the name of Carl as an alternate. She believes that strangers, posing as her parents, will not tell her the 'truth' about her origins, so that she suspects her 'real' ones are dead, and has thought of investigating further. Her 'mother' and 'sister' have impersonated her; she believes that a double of herself was seen in a different city.

Her first love, at 11 years, was another girl in hospital; the first male love, at 15 years, 'proposed marriage' but his parents intervened, spiriting him off to marry someone else. Several other men have 'proposed' to her. She recently imagined she was the object of affection of a Royal Canadian Mounted Police officer. She writes sexually suggestive letters and calls him daily. Mrs A published a book of verse abounding in themes of loneliness and sexuality in a vanity press.

The patient exhibited a generally euphoric distractible air, thought disorder, rapid pressured speech, derailment, neologisms, and clang associations, without hallucinations. The cognitive, physical and laboratory examination were essentially normal, as was the EEG.

B repeated his mother's persecutory and erotic delusions and was suggestive to somatic symptoms but did not maintain her Capgras syndrome or the somatic delusions with respect to her body. He was able to name only minor physical differences between the two of them, and knew that both he and his mother have the same birthmark on their chests. He was unwanted and although his milestones were normal, Mrs A wondered if he was 'slow'. He was extremely passive, with little reaction to events. He has not had any serious illnesses nor ever required admission to hospital. The boy was bright and friendly without thought disorder, depression or cognitive disturbance; affective range and expression were preserved. Physical examination was normal. His Wechsler Intelligence Scale for Children – Revised (WISC-R) Full Scale IQ was 111 (performance 95, verbal 123). His educational attainment was relatively good, considering his frequent school absences. Children's Aid has been extensively involved with trying to assure school attendance and compliance with treatment, including individual psychotherapy for him, to encourage separation and independence.

Discussion

While Mrs A satisfied the diagnostic criteria for a schizophrenic disorder, paranoid type, the preservation of affect, grandiosity, elation and lack of negative symptoms made schizoaffective or atypical bipolar affective (manic type) disorder, strong alternative possibilities; as she was not examined in an acute state, it was difficult to determine exactly how her delusions were related to mood.

Mrs A's disorder arose soon after B's birth, and she had several periods in hospital before he reached the age of three. They were abandoned to an isolated, insular and impoverished life. B, while somewhat passive, did not maintain all of his mother's delusions. Interestingly, he showed that he had incorporated her behaviour by responding to and adopting substitute, alternative names. He maintained some separateness by an identification with his father, aspiring to the same profession. In view of B's ability to appreciate that some of his mother's beliefs are untenable, and his intelligence and capacity to form relationships outside the symbiotic bond with his mother, as well as their mutual affection, immediate separation was not advised. Working with school authorities and Children's Aid, attempts were made to strengthen contact with reality by individual therapy with the son and an alliance with his mother. Her cooperation with these measures has been variable, as has her own compliance with neuroleptic treatment; contact has been intermittently maintained.

Most reports of *folie à deux* show a pattern of dominance and submission. Nine-tenths occur in families, with the mother–child combination the second most common. The inducer or primary agent must be in close proximity, be a figure of authority or identification, and be in the early or less severe stages of psychotic decompensation. Children of psychotic parents have several types of disturbance, and the conditions favouring these include a symbiotic relationship; lower than average intelligence in the child; a close identification with the sick parent; suggestibility, especially in relation to bodily feelings; passivity or submissiveness; and a marked involvement in the psychotic manifestations of the parent. The 'parapsychotic reactions' mirror the parent's illness closely, disappearing when the child is permanently separated. The conviction with which the delusion is held varies between children, and in any particular instance depends on the presence or absence of the deluded parent or reality-oriented figures (Anthony, 1969). Social circumstances, particularly poverty and isolation, play a role in shaping these influences.

The Capgras syndrome frequently has an erotic colouration. When a spouse is the object of the delusion, the patient may believe he is committing adultery with the imposter (the Alceme complex). While Sims and co-workers (Sims & White, 1973; Sims & Reddie, 1976) reported patients with affective disorder who showed both the Capgras symptom and de Clérambault's syndrome, several more cases can be discerned than have been recognised in the literature. Krafft-Ebing (case 56) in 1905 reported on a manic woman who, in addition to the Capgras syndrome, had nihilistic, dysmorphic (broken nose) and erotic delusions (pregnancy, proposals of marriage made to her). Brill (1912) discussed a man with either schizophrenia or mania who had both Capgras and Frégoli delusions along with de Clérambault's syndrome. De Clérambault's syndrome is recorded by Evans *et al* (1982) with the Frégoli symptom and by Picard *et al* (case 2) (1958) with the Capgras symptom in probable affective disorder. Seeman (case 1) (1971), using the term 'phantom lover' syndrome, and Pande (1981), the incubus syndrome, report cases of Frégoli and Capgras symptoms respectively with schizophrenia.

Shraberg and Weitzel (1980) alluded to erotomania co-existing with Capgras symptom in epilepsy. Among the patients reported by Christodoulou and his colleagues, erotomania was seen with Capgras, Frégoli and intermetamorphosis symptoms.

The two delusions of substitution and of erotic pursuit discussed above are uncommon but not rare. Individually they have been reported along with diverse delusional themes; their own association seems to occur with grandiosity, multiple delusions and possibly with the manic phase of bipolar affective disorder.

De Clérambault's Syndrome in Organic Affective Disorder

Two Cases

Two patients with erotomania (de Clérambault's syndrome) associated with epilepsy and head trauma are presented. The delusion appeared during periods of mania or hypomania and partially remitted during depression or euthymia. Erotomania may be seen in a wide variety of psychotic conditions, including those that are organically based.

Erotic delusions include several related delusional disorders (Enoch & Trethowan, 1979). In the 1920s, de Clérambault described the most well known of these, pure erotomania. This syndrome is characterised by the 'fundamental postulate' of a woman having the conviction of being in amorous communication with a person of a higher social rank, who ws the first to fall in love and to make advances to her. Derived themes include beliefs that the object can never find happiness without her, his overt attachments or marriage are invalid, contact is made indirectly by means of his immense resources, his overt attachments or marriage are invalid, contact is made indirectly by means of his immense resources, his conduct may be outwardly paradoxical, and their relationship is universally acknowledged and approved. There is a precise sudden onset, strong affective colouration, tendency toward action, and a lack of themes not related to the principal object of the delusion (Enoch & Trethowan, 1979). Secondary or mixed forms of erotomania have shown a wide variety of other delusional themes, greater elaboration, and multiple or even non-existent love objects.

Erotomania has been classified as a variant of schizophrenia, as a paranoid disorder, as a separate disorder (*'les psychoses passionnelles*', passionate psychoses), as a non-specific delusion occurring in conjunction with a variety of psychoses, or even as an acceptable occurrence without psychopathological implications. DSM-III (American Psychiatric Association, 1980) restricts the delusions of the paranoid disorders to persecution or jealousy, thus excluding erotomania from this category. This nosological confusion is due in part to incomplete descriptions of pre-morbid history, personality and clinical phenomenology of many early cases, as well as to the lack of conformity of the derivative themes (Ellis & Mellsop, 1985). However, a mental disorder cannot be characterised by its content or cross-sectional picture alone; classification also depends on its form, associated disturbances of mood, course, outcome, aetiology, and response to treatment. We present two cases of erotomania in patients with organic affective syndromes.

Case descriptions

Case 1

Mrs A, a 39-year-old right-handed housewife, was evaluated after incarceration for harassment of a teenage woman. One year before evaluation, she began to exhibit severe mood cycles. At times she was depressed and manifested fatigue, withdrawal from contact with her family, anhedonia, poor appetite, worsening of mood during the day, crying, decreased memory and concentration, suicidal ideation and slowing of thoughts and movements. At other times she exhibited an exuberant mood, swam nude in view of others, impulsively attempted to buy a car and a house, and engaged in many futile and destructive projects.

Following one episode of depression she 'came to life' when B became a Big Sister to her daughter, claiming she and B had a special relationship sanctioned by God. Mrs A believed others were jealous of them; she and B could communicate their unbounded love without speech, and B was able to transmit thoughts into her mind. Mrs A offered her money and gifts. A crisis ensued when B ran away from her in a panicked state, after what seemed to be a homosexual advance. The young woman's father moved to cut off contact, but the patient tried to see her many times, telephoned, and sent letters and presents to the house. Violation of a restraining order resulted in a short incarceration.

The patient had been diagnosed as having epilepsy when at age six she had a generalised convulsion preceded by an abdominal aura; recurrent seizures occurred with fever and menstrual periods. The presumed aetiology was head trauma at two years of age, although three paternal second-degree relatives had epilepsy. She was treated with phenobarbital until 15 years of age, and thereafter with phenytoin. At the time the delusion began, she had been without medication for two years. Mrs A often had the sensation of numbing, with fading of external sounds, or had olfactory hallucinations; she denied formed auditory hallucinations.

Mrs A's development was normal, but she never developed friendships with others. She performed poorly in school, testing in the dull normal range, but managed to graduate from high school. She worked intermittently in clerical positions. She had been married for 14 years and had two children. She had regular pre-menstrual mood changes, including depression, withdrawal, irritability, and aggressiveness. Libido had vanished almost entirely, and she admitted to neither heterosexual nor homosexual activity. Her maternal grandmother had a mental illness of unknown type that required hospitalisation, and remitted in late life; no other family member had psychiatric disturbance.

On examination, she was alert and anxious and she had angry outbursts against her mother when the latter described the patient's behaviour. Language function was normal, though her verbal output was tangential. There was mild impairment in both verbal and non-verbal memory. Visual-spatial testing showed severe deficits and she made errors on frontal systems tasks. Wechsler Adult Intelligence Scale - Revised (WAIS-R) scores were in the low average range (Verbal IQ = 83, Performance IQ = 83). Psychomotor speed was normal. A right hemiparesis and exaggerated right-sided muscle stretch reflexes were noted. EEG demonstrated slow wave activity in the left temporal region. CT scan was normal. The patient refused treatment and her delusions persisted.

Case 2

Mr C was a 27-year-old right-handed male brought to hospital by his college roommates because of threatening and aggressive behaviour. The patient had a history of many episodes of head trauma with loss of consciousness. As a child he had suffered physical and sexual abuse in foster homes; 11 years prior to admission he sustained a non-penetrating gunshot wound to the head; three years prior to admission he was in a motorcycle accident, with two weeks of unconsciousness; and he had been in many fights in which he sustained brief loss of consciousness. Mr C had frequently used alcohol and a variety of illicit drugs (LSD, marijuana, phencyclidine, opiates) but was not intoxicated at the time of admission. He had previously been arrested for shoplifting, disturbing the peace, and possessing of illegal drugs.

When examined, the patient was expansive and grandiose. He stated that he would someday be "king of the world". His speech was pressured, intrusive, and tangential, and he made inappropriate sexual comments and inquiries. He exhibited flight of ideas and admitted to prior, but denied current, auditory hallucinations. His affect was angry and labile. Mr C had a history of many hospital admissions in the past for similar behaviour and had been treated with a variety of neuroleptic and antidepressant agents and lithium carbonate. Of these, only lithium carbonate had ameliorated his behavioural disorder. The patient had experienced brief episodes of depression, with tearfulness, hopelessness and suicidal thoughts, but he had made no attempts to kill or injure himself. The patient was adopted; no information concerning his biological family was available.

The patient had a persistent delusion that a woman acquaintance was in love with him but would not acknowledge it and appeared to reject him. He had made many attempts to contact her and had been ordered by the court to refrain from bothering her. He remained convinced that she drove by his apartment many times each day, and called him by telephone but would not converse when he answered. The delusion had persisted for several months prior to admission, and resolved during his stay in hospital.

Psychological assessment revealed normal language, memory, visuospatial abilities, abstraction, and concentration. His IQ was in the superior range. A neurological examination was normal.

The patient was treated with lithium carbonate (300 mg three times daily). His manic behaviour began to subside, but he left the hospital prematurely and was lost to follow-up.

Discussion

In the first case, a woman with bipolar affective disorder and partial complex seizures originating in the left temporal lobe, manifested a homosexual erotomanic state with the features of de Clérambault's syndrome. The delusion began during a hypomanic episode but did not continue into the depressive phase of her illness. In the second patient, de Clérambault's syndrome made its appearance during hypomanic episodes following repeated head trauma. Both patients met DSM–III criteria for organic affective disorder and manifested de Clérambault's syndrome during episodes of mania or hypomania.

There are prominent symptoms of affective disorder in many previously published reports of erotomania. Multiple episodes, a waxing and waning course, hypersexual behaviour or promiscuity, and grandiosity are common. Thymoleptic treatments have ameliorated the erotomania and the associated affective symptoms in many cases. Most patients have demonstrated an accentuation of their delusions with hypomania, and partial or complete remission with euthymia. The patients reported here also showed an association between mania and de Clérambault's syndrome that did not persist into the depressive phases of their illnesses.

Few cases of erotomania with organic aetiologies have been reported. One of the cases of '*érotomanie associée*' (de Clérambault, 1913) was a young man with probable frontal lobe injury who developed the delusions during an episode of elation. Of the six cases reported by Schachter (1977), case 1 had head trauma (with fracture of the right temporal bone) and case 6 exhibited symptoms consistent with epilepsy. Among eight patients described by Lovett Doust & Christie (1978), the delusions were linked in case 2 to prolonged ingestion of oral contraceptives, in case 3 to cortisone treatment, in cases 6 and 8 to alcoholism, in case 4 to left temporal lobe epilepsy, and in case 7 to a deep epileptogenic focus due to a sphenoid wing meningioma (laterality unspecified).

Psychiatric symptoms found in the idiopathic psychoses may be duplicated by mental syndromes with an identified organic basis. Organic delusional disorders are common and may be the sole manifestation of brain dysfunction. A large number of metabolic disturbances and structural disorders, particularly affecting the limbic and subcortical areas, have been implicated in producing organic delusional syndromes (Cummings, 1985). In addition to causing psychosis *per se*, the delusional content may be affected by the site of the lesion. Among patients with organic delusional disorders, most of those with Capgras symptoms have had lesions involving the right hemisphere, whereas a majority of patients with Schneiderian first-rank symptoms have had lesions involving the left hemisphere (Cummings, 1985). Too few cases of erotomania associated with focal brain disturbances have been reported to determine if the laterality of the lesion is significant; but like most other organic delusional disorders, the associated brain injuries have usually involved basal or temporal limbic structures. Epilepsy with partial complex seizures and temporal lobe foci appears to be particularly common among patients with focal lesions and erotomania.

Delusions may also accompany organic affective disorders, and patients with secondary mania commonly manifest mood-congruent grandiose delusional syndromes. Secondary mania has previously been reported in disorders similar to those noted in the patients reported here, including post-traumatic conditions, epilepsy, neoplasms, cerebrovascular disorders, and degenerative conditions (Cummings, 1985). The two patients described here, and de Clérambault's (1913) patient who manifested erotomania during a period of elation following head trauma represent the only reported cases of secondary mania with de Clérambault's syndrome.

The two patients reported here and the brief review of the association of erotomania with organic delusional disorders bear on the nosological position of de Clérambault's syndrome. The occurrence of erotomania in patients with secondary mania and in patients with neurological disorders without prominent affective symptoms has been documented. These observations strengthen the conclusion of Ellis & Mellsop (1985) that de Clérambault's syndrome is an aetiologically heterogeneous disorder and, like Schneiderian first-rank symptoms, may be seen in a variety of psychotic conditions. Specific treatment of the behavioural disturbance depends on the investigation and recognition of the underlying aetiology for the delusional disorder. In patients with affective disorder, erotomania is most likely to occur during manic periods, and the possibility of an organic aetiology should be considered in all patients with de Clérambault's syndrome.

Incidence Worldwide of Schizophrenia

SIR: The critical comment by Stevens & Wyatt (*Journal*, July 1987, **151**, 131–132) on the preliminary report of the WHO Collaborative Study on determinants of outcome of severe mental disorders (*Psychological Medicine*, November 1986, **16**, 909–928) contains a number of factual errors and inaccuracies.

(a) Nowhere in the report is "worldwide similarity of schizophrenic incidence" claimed (as Stevens & Wyatt suggest); rather, the findings of the study are interpreted by us as "suggestive evidence for a more or less uniform occurrence of a 'core' of schizophrenic manifestations in different populations" (p 927).

(b) The case-finding period of the study was two years, not one.

(c) The inclusion criteria were not "either a broad (ICD–9 or CATEGO S, P, O) or narrowly defined (CATEGO S+, Schneiderian, nuclear) schizophrenia", but "the presence of a clinical diagnosis of schizophrenia (ICD 295), paranoid psychosis (ICD 297), reactive psychosis, paranoid and unspecified (ICD 298.3, 298.4, 298.8), unspecified psychosis (298.9), or one of the CATEGO classes S, P and O" (p 915).

(d) Table 6 of our paper contains data on the percentage distribution by age group of the cases in each of the 13 study sites; there is no way of inferring from such a table "large differences in age-specific incidence rates in the samples", as Stevens & Wyatt do.

(e) Figure 2 of our paper refers to *all* the patients in the study, and not to the cases in developing countries only.

(f) The reference to "inclusion of alcohol and drug-related psychoses by the authors" is misleading; in fact, we included patients with paranoid and hallucinatory illnesses associated with alcohol and drug use (ICD 291.3, 291.5 and 292.1) without evidence of organic features, provided that their symptomatology fell into one of the above-mentioned CATEGO classes. There were altogether 12 such cases (out of 1379). Brief confusional states, for example, were excluded.

Such misunderstandings aside, Stevens & Wyatt contest the significance of the findings on two grounds. First, they question the validity of the ICD–9/CATEGO diagnostic criteria employed, mainly for their lack of an in-built minimum duration requirement that would automatically restrict the diagnosis of schizophrenia to cases in which the psychotic symptoms tend to persist (as required in the DSM–III and, to a lesser degree, RDC). Secondly, they query the validity of the conclusion that, among the study subjects identified by the ICD–9/CATEGO criteria in the developing countries, there is a relative excess of patients who recover or show a milder course of the illness than symptomatologically similar patients in the developed countries.

The first point concerns the debatable issue of the diagnostic definition of schizophrenia: should it exclude, by introducing an arbitrary cut-off point, cases of recent onset that otherwise meet widely accepted descriptive criteria of the syndrome? While such *a priori* exclusion might be justified in selecting homogeneous patient samples for genetic or other biological studies, it would be totally inappropriate for epidemiological research which must take heed of the entire range of variation, temporal and descriptive, of the condition in a given population.

In designing the study, we explicitly adopted a stage-wise diagnostic approach which, at the level of primary screening, started with a 'broad' set of criteria aiming to minimise the chance of erroneously rejecting 'true' cases. Once the patients meeting the 'broad' criteria were fully assessed, more stringent CATEGO classification rules could be applied, including those defining the class S+ which is characterised by Schneiderian first-rank phenomena. The CATEGO classes are based on an assessment of symptomatology, and course is not part of their definition. However, the pattern of course and the duration of illness episodes were meticulously evaluated on the basis of previous history and follow-up data, and can be plotted for each level of the symptomatological definition. We consider this separation of the phenomenological from the temporal axis to be an asset, rather than a liability, in this kind of research, as it provides an empirical framework in which alternative diagnostic concepts can be tested.

Stevens & Wyatt doubt the validity of the diagnostic procedures employed in the study, and suggest that the study population may represent a heterogeneous collection of disorders. In particular, they suspect that the patient samples in the developing countries contain a high proportion of acute, transient psychoses which may be aetiologically different from the rest of the disorders classified as schizophrenia. In the WHO patient sample there was, indeed, considerable heterogeneity as regards course and outcome, but surprisingly little in the presenting symptomatology. This is clearly illustrated by the PSE symptom profiles (Figs 5–7 of our paper), for both the 'broad' definition of the disorder and the S+ patients. Insofar as the brief transient psychoses are symptomatologically different from schizophrenia of an acute onset, very few such cases would have slipped into the study through the PSE/CATEGO 'sieve'. However, similarity of the symptom profiles apart, there are other reasons to think that the disorders identified in the different centres belong to one category, whatever diagnostic label we put on it. In all study areas the age and sex-specific distribution of onsets followed similar patterns, characterised by an earlier onset in men than in women, while the aggregate incidence rates were very close to one another in the two sexes. This was true for both the 'broad' and the 'restrictive' definition of the cases, which reinforces our conclusion that the 'restrictive' CATEGO class S+ simply picks out the more florid schizophrenic illnesses, and does not identify a special syndrome.

The first contact incidence of schizophrenic disorders meeting the above criteria could be reliably estimated in 8 out of the 13 study areas. Two of the 8 areas were in the North of India: the city of Chandigarh, and a rural area near Chandigarh. The differences between the rates of the 'broadly' defined schizophrenic illnesses were statistically highly significant, and this is clearly stated in the report. However, the differences between the rates of occurrence of S+ type cases were not significant. The largest difference in the 'broad' rates was that between the rural area in India (4.8 new cases per 10 000 population at risk per year) and Honolulu, Hawaii (1.6 cases), a threefold difference. Although statistically significant, a difference of this magnitude in the observed rates of a low-incidence disorder such as schizophrenia is epidemiologically almost negligible.

We agree with Torrey (*Journal,* July 1987, **151,** 132–133) that none of the study sites which provided the incidence data belong to the few areas in the world where exceptionally high, or exceptionally low, prevalence of schizophrenia has been reported or suspected. We have no reasons to dispute the existence of pockets of unusual population frequency of schizophrenia, and incidence surveys in such areas would be highly desirable. Our conjecture, however, is that the incidence rates found in the WHO study represent a fair approximation to the typical, or modal, frequency of occurrence of schizophrenic disorders in most parts of the world (without being "worldwide").

As to the more favourable course and outcome of schizophrenic disorders in the developing countries, the new data do indeed support the earlier conclusions of the International Pilot Study of Schizophrenia. Table 11 of our paper shows that, independently of any differences concerning the proportion of acute onset schizophrenia (which has a more favourable prognosis) in the developing countries and in the developed countries, Third World patients with an insidious, or gradual, onset of their illnesses had a milder pattern of course than patients exhibiting the same type of onset in the developed countries. To us, this represents strong evidence that the phenomenon exists, although at this stage it cannot be explained by any specific environmental factor.

In forthcoming publications, we intend to provide much more detail on the findings outlined in the preliminary report.

Depressive Disorder in Primary Care

SIR: Blacker & Clare (*Journal*, June 1987, **150**, 737–751) state that "only a proportion, probably less than 10%, of depressed patients in primary care are referred to psychiatric services".

A large proportion of the psychiatric literature is devoted to research into biological aspects of depressive illness and to clinical trials of antidepressants. Fifteen to twenty years ago, patients with moderate to severe depression were often directly referred to a psychiatrist before antidepressant treatment had been prescribed. During that time, and under those conditions, much pioneering work was carried out into the biochemistry of depressive illness. The situation today is somewhat different: patients are often referred to specialist research units, often within the university setting, only after a general practitioner has failed to obtain an adequate response with one or more antidepressants for periods of one to two months. Since Katona *et al* (1986) have pointed out that previous antidepressant treatment can affect biological variates for up to three weeks after withdrawal from the drug, researchers are investigating not the biological characteristics of depressive illness but the biological legacy of previous antidepressant treatments. In addition, they are also looking at a highly selected group of patients who are often half-way through their self-limiting episode.

The majority, if not all, of new antidepressant drug trials are carried out under the supervision of a psychiatrist in either an in or out-patient setting. Conclusions are therefore drawn from a population of patients who may have psychotic features or suicidal ideation and, as described above, are by definition often relatively treatment-resistant. While this traditional testing ground provides a stringent test of a new antidepressant, I feel that putative antidepressants should be tested in the general practice arena where one finds the full spectrum of depressive disorders.

I concede that such trials would be difficult to carry out. Indeed, my own preliminary survey has indicated a marked disinclination of general practitioners to test new drugs. The possibility of destroying the doctor/family relationship at the first sign of an adverse reaction was the most common reason.

It should be emphasised, as Blacker & Clare have done, that the situation may be somewhat different in the USA where one may bypass the general practitioner and contact a mental health professional directly. For this reason, biological and clinical trial data obtained in the USA in the last ten years or so may be more relevant than that obtained in the UK.

Perhaps closer collaboration between psychiatrists and general practitioners and their respective Royal Colleges could once again ensure that pioneering research is carried out in the UK.

Khat-induced Paranoid Psychosis

SIR: As my article of 1945 was perhaps the first on the subject of khat-induced psychosis (Carothers, 1945), and since the course of the illness in the two cases there described differed markedly in one respect from that described by Dhadphale & Arap Mengech (*Journal*, June 1987, **150**, 876), I would like to add a comment to this discussion. The latter writers saw no relapses in any of their 15 patients, whereas one of my patients suffered two relapses requiring readmission within a year, and the other had three such relapses within 13 months. In explanation of this discrepancy, I can only surmise that by the time of the later article some supervision after discharge was maintained in Kenya: a supervision which was not available there in 1945.

However this may be, it seemed to me then (and does so still) that, since the great majority of khat chewers suffer no obvious ill-effects, these florid psychoses occur in people who are mentally vulnerable and who do require some organised support when discharged from hospital.

HIV and Informed Consent

SIR: I read Davies's letter (*Journal*, June 1987, **150**, 881–882) with interest. As the natural history of human immunodeficiency virus (HIV) infection unfolds, so the neuropsychiatric complications are recognised with increasing frequency. Psychosis may accompany HIV infection (Thomas *et al*, 1985; Rundell *et al*, 1986; Jones **et** *al*, 1987) or may be the first presentation of the acquired immunodeficiency syndrome (AIDS) (Thomas & Szabadi, in press). Indeed, HIV dementia may be the first and only manifestation of HIV infection (Navia & Price, 1987).

In psychotic patients who come from high-risk groups (promiscuous homosexuals, bisexuals, drug addicts, prostitutes, and haemophiliacs), HIV infection must be considered in the differential diagnosis. A clinical dilemma is posed when such individuals are unable to give informed consent to HIV testing (or understand the pre-test counselling, etc.) by virtue of their disturbed mental state.

Venepuncture without consent on an informal patient is a battery and a form of trespass on that person. Should those psychotic individuals who are unable to give consent or are irrationally refusing (as a result of their mental disorder) be detained under Section 2 of the 1983 Mental Health Act for the purpose of assessment and further investigation of their mental illness?

I have had personal experience of two psychotic patients who were HIV positive; it was necessary to detain both under the Mental Health Act, as one had tried to throw himself in front of passing vehicles and the other had threatened to cut his mother's throat. It is envisaged, however, that there will be some psychotic individuals (from high-risk groups) who are not thought to be a risk to themselves or others but who are unable to give informed consent. In these individuals it would seem inappropriate to recommend detention under the Mental Health Act for performing a blood test. In such cases, would a doctor be ethically justified in removing some blood from a co-operative patient for HIV screening without obtaining informed consent?

The advantage of knowing HIV status is apparent. Treatments for HIV infection are available, but as yet are only palliative. The infected individuals can be identified and appropriate precautions taken, if not already being practised. A negative test should lead to further investigation of the aetiology of the psychosis.

Behavioural Psychotherapy in General Practice (Marks, *Journal*, May 1987, 150, 593–597) – A Response

SIR: It is widely believed (by several people, in fact) that psychiatry is a highly specialised business. This notion is based upon quite false assumptions that I need hardly trouble you with here. Literally hundreds (possibly thousands) of Girl Guides, St John's Ambulancemen, swimming bath attendants and the like have found it quite easy to acquire what at first sight appear to be complex skills without any time-wasting basic science training.

In fact, you can take it from me that psychiatry is beset by unnecessary and restrictive mystique, whereas within days (possibly hours) all that needs to be known about the subject can be imparted to thousands (if not millions) of quite ordinary people with little knowledge of anything particular already in place, so to speak.

We have recently shown, for example, that the therapeutic silence in group therapy is a skill mastered easily by cohorts of bus drivers although, admittedly, they may have been a taciturn bunch to begin with. Our classes in writing benzodiazepine prescriptions, too, have clearly demonstrated that, within just a few minutes, most cloakroom attendants have grasped a skill hitherto thought to require years of training.

It is true, of course, that we have had a bit more difficulty in training a group of unemployed geography supply teachers to recognise schizophrenic thought disorder, but this may well have been due to some confusion on our part about this strange condition.

The evidence for what I'm saying comes from my own long experience, you understand. But you can take it from me and my staff that there is really nothing to it and we could within weeks (or possibly days, in an emergency) turn out thousands (possibly millions) of. perfectly well-qualified psychiatrists busily and successfully treating just about anything you care to mention.

Frankly, I can't see what all the fuss is about.

Female Sex Offenders

SIR: In O'Connor's interesting account of female sex offenders (*Journal*, May 1987, **150**, 615–620), one example stands out and cannot go unremarked.

Case 6 is that of a young woman and her 3-year-old daughter who, after parting from an alcoholic and violent husband and father, were living with an affectionate man whom the mother was about to marry. The "offence" consisted of the man on *one occasion* allowing the child to hold his penis, with the mother's agreement. Intercourse between the couple had at times occurred, as probably in many families, in the small child's presence.

The result of these events was, not that counselling was offered to the parents, but that the mother and her cohabitee were imprisoned for two and three years, respectively, thereby presumably leaving the child parentless. It seems the mother had been seen by a psychiatrist (not the author) at the time of the trial and "No psychiatric abnormality was found...".

O'Connor could have helped us greatly by indicating the steps taken by the first psychiatrist to support this family and prevent the Court from depriving a child, at a vulnerable developmental stage, of her parents, when these were apparently affectionate and cared both for her and each other. Some discussion of how the sexual behaviour within this family came to be discovered, and defined as an "offence", would also have been of interest.

SULA WOLFF

University of Edinburgh Department of Psychiatry
Royal Edinburgh Hospital
Morningside Park
Edinburgh EH10 5HF

SIR: The woman involved (Mrs C) sometimes looked after a neighbour's children. Mrs C's child told these children what had happened and they told their mother, the neighbour. She in turn informed the NSPCC, and they informed the police and social services.

Mrs C and her co-defendant were both remanded on bail for the six months before the case came to Crown Court. The child was taken into foster care and Mrs C saw her twice weekly.

Mrs C, her co-defendant, and the child were assessed on one occasion while on bail by a child psychiatry team experienced in child sexual abuse cases. In their report they expressed a willingness to continue seeing them should the parents be at liberty, but they expressed serious reservations about the child being returned to Mrs C if her co-defendant was living in the same house until a long period had elapsed.

At Crown Court Mrs C and her co-defendant pleaded guilty and were both remanded in custody for the preparation of reports. At time of sentencing, the report of the child psychiatry team, a probation report, and a psychiatric report were all available to the Court.

I too was surprised by the sentence in this case.

Comparative Trial of a New Antidepressant

SIR: The trial by Levine *et al* (*Journal*, May 1987, **150**, 653–655) had a "double blind" design. However, tremor was four times more common with fluoxetine than with imipramine ($P < 0.01$). Does it not occur to the authors that this may have undermined the double-blind design? A notional double-blind design may be subverted by side-effects. This possibility may be addressed empirically by inviting participants to guess the patients' drug status on each occasion when drug effects are being assessed; observed guesses can then be compared statistically with those to be expected by chance, thereby providing a measure of how "double-blind" the study is.

M. L. ROBINSON

Hesketh Park Hospital
Southport
Merseyside PR9 0LT

SIR: It is theoretically possible to undermine the double-blind design of clinical trials when there is a significant difference in response between the trial and comparator drugs. This can be either a measurable or easily-detected difference in clinical efficacy or in the side-effect profile.

It has been an unfulfilled ambition of mine to carry out a clinical study when the former occurred in favour of the new compound. In this study a significant difference was elicited with one minor side-effect which did not influence compliance, and little attention was paid to this effect until the results were analysed.

Clearly it would be possible to attempt to break a double-blind design if the difference were obvious. As this is not the intention of double-blind studies I can see little advantage being gained by attempting to break the code in advance of completing the trial. If there is any advantage in doing so I am sure that there would be many such studies where this might be more easily accomplished.

Lithium in the Treatment of Aggression in Mentally Handicapped Patients

SIR: The report of a double-blind trial of lithium in aggressive mentally handicapped patients (Craft *et al, Journal,* May 1987, **150,** 685–689) is important. A paper published seven years ago was similar in content (Dale, 1980). Both report on patients who had been in hospital for varying lengths of time (Craft, 0–49 years; Dale, 2–42 years), the average stay being 12 years in each. My study was a retrospective one, while that of Craft *et al* was prospective. The methods of analysing the findings are very different, but the results remarkably similar.

Lithium therapy must now be seen as having a definite place in this difficult group of patients. If given earlier in the condition instead of as a treatment of last resort, as it is now, then the necessity of long-term admission may be obviated. This would be of benefit to patient, relatives, and staff.

Lithium is a relatively simple and safe form of treatment in skilled hands, which could have wider use in this clinical context. The economic advantages which would accrue from its early use have some relevance too.

Compensation Psychosis

SIR: White *et al* (*Journal,* May 1987, **150,** 692–694) report the case of an episode of paranoid psychosis in a patient who had suffered concussive head injury and had become involved in litigation for compensation; his delusions centered around the latter. While post-traumatic psychoses are rare, paranoid ideation occurs frequently in the course of prolonged litigation.

In the introduction to their paper the authors mention a number of old and recent aetiological issues which deserve attention. Quoting White (1981), they state that "there was no statistical difference between those victims in whom the accident had given rise to litigation and in whom the case was still proceeding and those victims where compensation was not an issue". This may be correct as far as statistical evidence goes. However, the most important factor should not be overlooked, i.e. the responsibility for the accident and its consequences. The majority of accidents in which compensation is not an issue are those occurring in the home, in sports, and on the road (in the latter case the accident victim being the responsible party). The neurotic disability process does not start with litigation for compensation, which is a much later development; it starts as soon as the victim realises that someone else (employer, property owner, driver, etc.) is at fault, followed by the attending physician's mistaken belief that he is helping his patient by ordering rest from work and activity. Compensation is but one significant factor in the development and maintenance of post-traumatic disorders. Other equally important factors subsumed under the heading of 'secondary gains' from disease are attention, protection, and over-solicitousness on the part of the patient's environment that constitute a serious obstacle to response to treatment, spontaneous recovery, and rehabilitation. Occupational and marital dissatisfaction, latent before the traumatic event of the accident, may frequently manifest themselves as symptoms of the neurotic disorder.

In analogy with the notion of iatrogenic disorders I have coined the term 'nomogenic disorders' (from the Greek *nomos* – the law) (Tyndel, 1974) to describe those psychopathological disorders in which the law and its application is playing an aetiological role in the development, enhancement, and perpetuation of these disorders. The case reported by White *et al* represents a typical example.

Tuberous Sclerosis and Psychosis

SIR: This year the *Journal* has published two case reports of psychotic behaviour in tuberous sclerosis (TS) (Lawlor & Maurer, *Journal,* March 1987, **150,** 396–397; Clarke *et al, Journal,* May 1987, **150,** 702–703). These suggest that psychosis in tuberous sclerosis is a rare manifestation of a rare disease. We draw attention to our study of the psychiatric status of 90 children with tuberous sclerosis (Hunt & Dennis, 1987). At five years of age, over 50% showed psychotic behaviour (predominantly autistic), 59% were hyperkinetic, and 13% were severely aggressive. Psychosis therefore appears to be a common rather than a rare manifestation of the severe effects of the TS gene.

Furthermore, a conservative estimate of the prevalence of TS, for which there is no absolute marker, is 1 in 15 400 for children under 5 (Hunt & Lindenbaum, 1984). The disorder is thus not as rare as previously thought.

Our study of TS leads us to propose that profound language delay, severe impairment of social interactions, hyperkinesis, and sleep disturbance constitute a behavioural phenotype. Although not pathognomonic, this occurs so frequently in tuberous sclerosis that we consider that it should be included among the diagnostic criteria for the disorder.

Amnesia: Organic and Psychogenic

SIR: In his review of amnesia (*Journal*, April 1987, **150**, 428–442) Kopelman fails to deal with the questions of whether individuals who say they have lost their memory, in the absence of any organic cause, are truly amnesic, and of how genuine amnesia may be distinguished from feigned amnesia. He seems to assume that all those suffering from what are often referred to as fugues and hysterical amnesias have genuinely lost their memory.

The question of psychogenic amnesia seems to have attracted little interest in recent years, and it is significant that many of the publications quoted by Kopelman are more than 40 years old. In the Podola case (Furneaux, 1960) the genuineness of claimed amnesia was rigorously probed during several days of a highly publicised trial, on the issue of fitness to plead. Several psychiatrists and other doctors gave evidence; some of them provided the unedifying spectacle, to which psychiatry seems uniquely prone, of disagreeing with one another about the most basic symptoms of the condition about which they were giving expert testimony. Leigh stated that a patient with hysterical amnesia for the whole of his life would not be able to recognise common objects or tie his shoe laces, but Stafford-Clark said that this was entirely wrong. In fact, Podola had made a number of apparent blunders tending to show that he did remember things he claimed to have forgotten, and the jury found his amnesia to be feigned.

The views of the late Sir Charles Symonds (quoted by Merskey, 1979) are of interest:

> I suspect also that all so-called hysterical fugues are examples of malingering. Forty years ago a young man was brought to this hospital (the National Hospital, Queen Square) as an out-patient to B Room, where I was working, with loss of memory for a period of a week. I had a heavy load of patients and it was a hot afternoon. I did not want to admit him and could not face the prospect of a prolonged psychotherapeutic session. I said to him "I'm quite sure you can remember if you try: here are paper and pencil. Write me out your story, and I will do what I can to help you". With that I put him into the side room, closed the door and went on with my work. At the end of my session I had forgotten about him, but as I was about to leave there was a tap on the door of the side room and he emerged with two sheets of close written foolscap.
>
> His story was this. He worked in a shop in Birmingham, had recently married, and took £10 from the till to cover the expenses of his honeymoon. He had, as he said, "borrowed" it. On his return home he found that a previous misdemeanour had been discovered, and that he had been sacked. So there he was with no prospect of repaying the £10 before his theft would be discovered. He concluded that the only way out was suicide and that the right way would be to jump off the cliffs at Lands End. So he made his way down to Lands End but there was no suitable cliff. It was dark and cold. He went to the nearest police station and declared that he had lost his memory and knew neither his name nor address. He was then transferred to hospital at Penzance and subsequently referred to Queen Square.
>
> Since then I must have seen half a dozen cases of so-called hysterical fugue in private practice and have adopted the following plan. I have said to the patient "I know from experience that your pretended loss of memory is the result of some intolerable emotional situation. If you will tell me the whole story I promise absolutely to respect your confidence, will give you all the help that I can and will say to your doctors and relatives that I cured you by hypnotism". This approach has never failed, and I have been told some dramatic stories".

It is not uncommon for loss of memory to be claimed for the period immediately surrounding the commission of an offence, such as shoplifting. In these cases it usually becomes clear that the person concerned does have some, possibly vague, recollection of events, and such clouding of memory as is present can often be explained by the effects of drugs or alcohol, or both. Classical 'hysterical amnesia' seems to be (like other dramatic 'hysterical' symptoms) even rarer now than in the past, and I have not seen a case for many years. But was it not the case that when such patients arrived at the casualty department, all identifying articles had usually been carefully removed?

I have never been able to satisfy myself of the genuineness of claimed psychogenic amnesia and suspect that many psychiatrists share this view, even though they might not feel as confident as Symonds in dealing with such patients. Do many psychiatrists now believe that genuine psychogenic amnesia exists, and if so, is that belief sustained by anything more than credulity?

Physical Examinations by Psychiatric Trainees

SIR: Rigby & Oswald (*Journal*, April 1987, **150**, 533–535) draw attention to the unsatisfactory physical examinations recorded by psychiatric trainees. How much such shortcomings contribute to missed physical morbidity is uncertain.

Psychiatric trainees, and maybe their seniors, also pay scant attention to aspects of the clinical method which yield more information than physical examination. Hampton *et al* looked at the relative importance of history, examination, and investigations in making a diagnosis in medical out-patients. In 87% of patients, reading the referring letter and taking a history sufficed. Examination only made a significant contribution in 7%.

I have reviewed the case notes of 20 patients randomly selected from those admitted to this hospital in 1986. In one case an incomplete systems review of physical symptoms was recorded. The biological symptoms of depression were the only physical complaints mentioned in the other notes. In all cases a physical examination and a coherent history, from patient or relative, were recorded.

Hampton *et al* state that their findings cannot be directly applied to other settings, but it seems unlikely that physical examination could produce more information than questions about physical symptoms in the patients seen by psychiatrists. The arguments of Oswald & Rigby that all relevant data should be recorded apply equally to examination and history-taking.

It may be a council of perfection, but should not psychiatrists be encouraged to ask about and record physical symptoms? The skill of taking a medical history should be as enthusiastically preserved as that of performing a physical examination.

Depression, Dementia, and Disability in the Elderly

SIR: The studies of Good *et al* (*Journal*, April 1987, **150**, 463–470) and Griffiths *et al* (*Journal*, April 1987, **150**, 482–493) require some comment, since acceptance by the *Journal* may lead some readers to suppose that they represent a significant contribution to psychiatric epidemiology. Good epidemiological research is founded on well-defined samples, appropriate methods, and interesting questions; these studies are seriously inadequate in every respect.

Sampling: Both studies are based on data obtained from a sample of 200 old people registered with a group practice, so these subjects are not "community elderly" as asserted by Good *et al*. In the first place, elderly people registered with a GP are likely to be more alert and healthy than those who are not so registered (Murphy *et al*, in press). Secondly, although it is unclear just how the subjects were recruited, according to Griffiths *et al* only a proportion were randomly selected from the practice list. The remainder (we are not told how many) were enrolled into the study when they attended the health centre, which introduces a serious bias. Many elderly people with psychiatric disorders are unknown to the health services, and those that present usually do so with additional physical or behavioural problems. It is hardly surprising, therefore, that the authors should have found an association between their measures of dementia, depression, and disability. Thirdly, their subjects were all able to get to the health centre for assessment; this obstacle will have excluded many of those with moderate and severe depression or dementia as understood by psychogeriatricians. Findings based on this peculiar sample cannot be extended to the elderly population in general.

Methods: The authors used a questionnaire derived by them from the Hamilton Rating Scale for Depression (HRSD) which they describe as the "most appropriate in community studies in the elderly". They cite Kearns *et al* (1982) in support of this, but in fact Kearns *et al* were at pains to point out that their observations on depression rating scales in in-patient samples could not be extended to out-patient or community settings. The HRSD is valid only as a measure of severity in established cases of depression; its usefulness with non-cases remains to be demonstrated, particularly in the elderly. There is much emphasis on somatisation and psychomotor symptoms in the HRSD, and positive responses to these items may well be related more to physical illness than to depressed mood in this age group.

The authors seem to have eschewed any sort of validation – they comment on the "confused" classification of depression in psychiatry, and assert that "depression and dementia here refer to categories defined according to . . . rating scales and not to clinical diagnoses". However, they quote "prevalence" figures, and seek to impress upon us the clinical relevance and "retrospective justification" of their factors and clusters; these might have been more convincing had they provided us with some initial validation of their cut-off criteria. I was particularly struck by their comment that "a score of 0–13 [on the HRSD] would include all normals but would not exclude all depressed patients – have they not heard of false positives? It is a pity that no psychiatrists were involved in their study.

Aims: The declared aims of Griffiths *et al* were to determine the association between depression, dementia, and disability, and to identify patients at risk in the community. The first aim has been thwarted by their inadequate sampling and methodology; the second seems to have been abandoned, since there is nothing in their paper that relates to it.

Good *et al* are particularly coy about the purpose of their study, and no underlying hypothesis is discernible. Implicit in their introduction is the potentially interesting notion that normal subjects and those with depression have a common structure to their symptoms, but they have not tested this useful null hypothesis with separate analyses of normal and depressed groups. Rather, all we are given is a description of the symptom structure in the group as a whole, quite unrelated to any clinical or operational diagnoses.

Had the authors clarified their aims at the outset they might have chosen their sample and methods more appropriately, and their fine display of multivariate techniques would have been to some purpose. As it is, their efforts merely demonstrate yet again that in epidemiological research at least you can't make a silk purse out of a sow's ear – not even with cubic polynomials.

Kearns, N. P., Cruickshank, C. A., McGuigan, K. J., Riley, S. A., Shaw, S. P. & Snaith, R. P. (1982) A comparison of depression rating scales. *British Journal of Psychiatry*, **141**, 45–49.

Murphy, E., Smith, E. R., Lindesay, J. & Slattery, J. Excess mortality in late life depression. *British Journal of Psychiatry* (In press).

Sir: We were interested in the comments made by Lindesay, but consider that most of the points he raises would be answered by a more careful reading of our original papers. He reiterates reservations about the sample which we had been at pains to point out in our presentation. His criticisms underline the epidemiological problems we discussed.

We avoided arguing from the particular to the general – the subjects were 'elderly in the community', not "community elderly" as Lindesay alleges we asserted – there is a semantic difference. We emphasised that our sample was a 'good' group, described in terms of disability, and suitable for comparison with groups such as the housebound. Nowhere do we purport that the sample was random.

Our selection of the HRSD was based on a wide examination of the literature, and was not predicated on Kearns *et al* (1982) alone.

The identification of patients at risk is implicit in the final paragraphs of the discussion of Griffiths *et al* (*Journal*, April 1987, **150**, 482–493).

In Good *et al* (*Journal*, April 1987, **150**, 463–470) we stated that separate results were not presented for subsets of the sample, although the factor structure of the 'normal' subjects was similar to that of the whole sample; it would have been of little value to present a statistically non-significant analysis of the small depressed group.

Asperger's Syndrome

SIR: There is controversy about the validity of Asperger's syndrome (AS) (Schopler, 1985; Volkmar *et al*, 1985; Wing, 1986). Although first described in 1944, interest in the condition was revived by Wing (1981). Individuals with AS are described as having: pedantic, lengthy speech; stereotyped speech; impaired non-verbal communication; Aprosodic speech; peculiar social interaction; lack of empathy for others; repetitive activities; resistance to change; clumsy or stereotyped motor movements; and hypertrophied skills or circumscribed interests. A number of investigators have conceptualised AS as part of an 'autistic spectrum', and note that no behavioural distinction can be made between AS and higher-level autism (Schopler, 1985).

We recently re-read "Children with circumscribed interest patterns" (Robinson & Vitale, 1954). This paper is of interest not only because of the lucid clinical case descriptions presented, but also in terms of the discussion following the paper by Kanner. None of the patients described fit DSM–III criteria for autism as applied by us to case report material. Furthermore, Robinson & Vitale, as well as Kanner, see these children as being different from autistics. The defining features of the children described include pursuit of special interests restricted to certain areas which have special value to them. There is an avoidance of involvement in other conceptual, social, or interpersonal areas.

We applied the above descriptive criteria for AS to each of these patients. Cases 1 and 2 were positive for four criteria each, with insufficient data for the other six criteria. Case 3 was positive for five criteria, with insufficient data for five. Interestingly, case 1 exhibited severe phonic tics (Kerbeshian & Burd, 1986). With the data available, we can only state that the cases as presented are not inconsistent with AS.

Kanner's comments may be of some general value in the controversy regarding the syndromic specificity of AS. He argues the value of an atheoretical description, and cautions against putting "the interpretive cart before the semeiologic horse". He notes that circumscribed interest patterns as a syndrome may also be found in children whom we today might describe as hyperlexic, in obsessive children, and in schizophrenic children, as well as in autistic children. Finally, Kanner lauds Robinson & Vitale for their attempts to single out specific clinical patterns as a basis for diagnostic categorisation.

It is with Kanner's thoughts in mind that we are concerned about the potential diagnostic reification of conceptualisations such as "good-prognosis autism" or "autistic spectrum". Whether AS represents a point of confluence of one or more primary syndromes, or whether it coheres as a primary syndrome itself, should be decided by studies based in data, and not by opinion. We should strive toward having the semeiologic horse pull the interpretive cart.

Hepatitis B and Mental Handicap

SIR: At the recent symposium on hepatitis B held in London, a warning was issued that hepatitis B was the most serious form of viral hepatitis, and it was said that safe and effective vaccines were available which could prevent infection and so prevent most cases of liver cancer.

This is a timely reminder to all colleagues who work in the field of mental handicap to be alert towards hepatitis B virus, which is endemic among the mentally handicapped population, particularly now when the mentally handicapped live for much longer (Carter & Jancar, 1983) and a number of patients have been discharged from hospitals.

Between 1976 and 1980 all the patients in the seven hospitals and seven hostels for the mentally handicapped in the Bristol area were screened for markers of hepatitis B infection. Of 2239 patients, 123 (5.5%) were carriers of hepatitis B surface antigen (HBsAg) and a third of these were 'infectious' (negative for antibody to hepatitis B_e antigen). Patients with Down's syndrome were 18 times more likely to be 'infectious' carriers than those without, and male patients were six times more likely to be 'infectious' carriers than female patients.

The carrier rate decreased with age, but the proportion of carriers who were hepatitis B_e antigen positive were unaffected by age (Clarke *et al*, 1984).

It is therefore very important that monitoring of the hospital and community population of the mentally handicapped for hepatitis B is maintained and that vaccination of patients and staff takes place when appropriate.

Nurses' Attitudes to Psychiatry in a General Hospital

SIR: Liaison psychiatry and community care appear to be having a field-day in academic psychiatric circles. But to be practically successful the ideas must percolate through to the professionals we work with: physicians, nurses and para-medical staff. Their acceptance of such ideas will be determined by the attitudes they already have towards psychiatry and psychiatrists. Hence the necessity for further clarification of these attitudes.

Thirty-five trained general nurses (SRNs) were surveyed using an attitude questionnaire (Townsend, 1978). A control group of 35 age and sex-matched nurses just beginning their training was also studied. Although the sample consisted predominantly of women, over two-thirds felt that women are no more likely to develop mental disturbances than men. Nearly nine out of ten supported the belief that adult mental disturbances can be traced to emotional experiences in childhood. Almost half genuinely thought that most suicides occur because of rejection in love. After doing an eight-week placement in psychiatry in a DGH Unit with rapid turnover and no long-stay provision, about 1 in 5 still felt that few inmates of mental hospitals ever leave hospital.

Regarding the work of the psychiatrist, two-thirds felt that we should show patients where their ideas are incorrect. After having participated repeatedly in multi-disciplinary ward rounds, a fifth continued to feel that the main job of the psychiatrist was to recommend hobbies and other ways for patients to occupy their minds. Curiously enough, two-fifths of the control group felt that a good psychiatrist acts like a father to his patients. Four-fifths of the trained group disagreed with this.

It was clear from the responses that among these nurses, a dichotomous view concerning physical and mental illness persisted. Over four-fifths of trained nurses saw little role of physical causes in bringing about mental disorder. A similar proportion also denied the role of poor diet in any manifestations of mental instability. This viewpoint is potentially dangerous, since the possibility of the elderly deprived/mentally ill presenting the mental symptoms because of subclinical vitamin deficiency is greater in a general hospital setting.

At a social level, a third of the nurses denied mental health the status of an important national problem. About half also felt that psychiatrists almost always have difficulty in telling whether or not a patient's mental disorder was curable.

In spite of all the methodological pitfalls of a questionnaire study, one message is clear. The resistance and mistrust towards psychiatry and psychiatrists is only marginally different now from what it was in the past. The days of total community care are imminent, and yet some of our colleagues are not aware of what psychiatry has to offer. While a review of the psychiatric training of general nurses is needed, a careful re-appraisal as to our own behaviour merits study.

Phensedyl Abuse

SIR: Interest in the abuse of ephedrine (Whitehouse & Duncan, *Journal*, February 1987, **150**, 258–261) and pseudoephedrine (Pugh & Howie, *Journal*, December 1986, **149**, 798) prompts me to report the occurrence of phensedyl abuse in a group of young men in a small country town (Midsomer Norton) and the treatment of an addict.

Phensedyl is a proprietary cough linctus available without prescription. Each 5 ml contains 7.2 mg of ephedrine hydrochloride, 3.6 mg of promethazine hydrochloride, and 9 mg of codeine phosphate. There are no reports in the literature of dependence on phensedyl, although one can only echo the contention of Whitehouse & Duncan that abuse of substances containing ephedrine occurs unreported in the UK.

Case Report: A 31-year-old single man requested help in stopping drinking 2–3 bottles (200–300 ml) of Phensedyl per day. He had been drinking this for 11 years, along with about 10 friends, most of whom were still abusing it. He had also abused *Actified* and intravenous amphetamines, but was not currently doing either. He had been in prison for two short periods for stealing to pay for his habit and, although on both occasions he had not undergone serious withdrawal symptoms, he had increased his consumption since then. He had no other psychiatric symptoms. It was calculated that 200 ml of Phensedyl contained 288 mg of ephedrine hydrochloride, 144 mg of promethazine hydrochloride, and 360 mg of codeine phosphate; these amounts were prescribed in tablet form as a daily dose on a reducing regime, and the patient was seen and counselled regularly over a seven-month period. He remained drug-free for a further four months, but his course since then has been one of intermittent Phensedyl abuse and abstinence.

Negative Interaction Between Lithium and ECT

Sir: We report a woman who developed a mild acute organic brain syndrome with normal serum lithium level, stopped lithium, recovered, and because of continuing depression was given ECT and then developed a severe confusional state.

Case Report: A 57-year-old woman with a history of recurrent unipolar depression was admitted to hospital following the death of her husband. Her father had suffered from depression, but had not sought treatment. He had taken to his bed for 10 years, mainly for depression, but eventually died of senile dementia, Alzheimer's type. There was no other family history of affective disorder. The patient had three children, but none proved to be supportive following the death of her husband.

She was admitted to hospital and treated initially with a variety of antidepressants, including dothiepin, mianserin, and Parnate, but could not tolerate amitriptyline or nortriptyline. Lithium was added to her regime, and although it initially seemed to help her depression she developed severe tremor, ataxia, and a mild confusional state. All medication was therefore stopped. She remained severely depressed and it was decided to give her a course of bilateral ECT.

After the first ECT she complained of mild myalgia and took to her bed, but recovered. ECT appeared to help her depression. However, after the second ECT she became severely confused, rambling, disorientated in time and place, and had a reversal of her sleep rhythm. She then had to be nursed in bed for about a month. She gradually recovered from her confusion and thereafter made a slow recovery. Her depression returned, but using small doses of dothiepin the depression gradually remitted over the next year. She is almost fully recovered from depression, but complains of a poor memory. There are no signs of any dementing illness.

The presence of an ECT-induced confusional state following an episode of lithium toxicity (but with normal serum level) has not been previously reported. While, in retrospect, it might have been more clinically prudent to have delayed ECT, the patient was in a state of very severe depression when this decision was made. Furthermore, we were unaware at the time that there might be any adverse reaction between ECT and lithium.

A few case reports suggest the possibility of such an adverse interaction. Hoenig (1977) reported a patient in whom ECT precipitated a severe encephalopathy, although the patient's serum lithium level was well below the toxic value. Remick (1978) reported a patient who was given ECT while on lithium therapy; after the fourth ECT she developed severe confusion and was incontinent. Six weeks after the resolution of her confusion she was once again treated with ECT, but this time with significant improvement of her depression and no confusion. In a third case (Weiner *et al*, 1980), lithium carbonate was introduced after a third ECT treatment and the patient developed a severe fluctuating confusional state.

In a retrospective controlled study of 25 patients who had both ECT and lithium, Small *et al* (1980) found that the lithium/ECT treatment group had more severe memory loss, atypical neurological findings, and a poorer response to ECT. These authors speculated that the patients on lithium might either be a more severely depressed group, or that there might be a true negative interaction between these two common methods of treatment.

Our patient and the patients reported by others suggest the latter, and we are presently investigating the possibility of a true negative interaction between lithium and ECT.

Structural Brain Lesions in Functional Psychosis

SIR: Findings pertinent to cerebral and cerebellar pathology and functional psychosis seem to be limited and contradictory (Hamilton *et al*, 1983; Wexler, 1980). It has not yet been proven, however, whether there is a significant aetiological relationship between organic pathology and psychiatric illness in general. We present two case reports of functional psychosis: one patient with bipolar affective disorder who had radiological evidence of cerebral and cerebellar atrophy, and another with a schizophrenia-like disorder who had cerebellar atrophy. They were both illustrated by CT.

Case Reports: (i) A 49-year-old woman without any personal or family history of neuropsychiatric illness became depressed at the age of 38, with symptoms of sadness, hopelessness, psychomotor retardation, decreased appetite and sleep, and a serious suicidal attempt. She was admitted to a psychiatric clinic, but within a few days her depression changed to a manic state with increased psychomotor activity, euphoria, loquacity, and delusions of grandeur. She returned to her normal state in about three weeks, but experienced a similar depressive and a manic episode six years later. We examined the patient during her third depressive episode, at which time she was treated with tricyclic antidepressives and lithium. At six-month follow-up, the patient showed a significant deterioration and was noted to have a cerebellar syndrome with symptoms of dysmetria, dysarthria and cerebellar ataxia. Serum lithium level and blood chemistry were normal. EEG revealed nonspecific dysrhythmia, but CT of the brain revealed diffuse cortical atrophy, ventricular dilatation, and cerebellar vermian atrophy. During the following two months her condition gradually merged into a dementia syndrome which was documented by psychological tests. Later she developed a paranoid-hallucinatory and delusional state. Finally, her schizophreniform manifestations improved, but the dementia remained unchanged.

(ii) A 24-year-old female had symptoms of hearing voices and talking and acting as if they were real. She also had fears of being harmed by others, and gradually became withdrawn. Her initial symptoms had occurred at the age of 15, and she was diagnosed as having an early onset schizophrenic disorder with symptoms of auditory hallucinations, persecutory delusions, delusions of reference, lack of interpersonal relations with flatness of affect, and finally autism. In spite of antipsychotic therapy, the patient's condition worsened and she became severely disabled and dependent on others. Over the past year all psychiatric symptoms disappeared, but she revealed several neurological deficits, including left central facial paresis, left hemiparesis, horizontal nystagmus, ataxia, and dysequilibrium, all of which were preceded by headache, nausea, and vomiting. Currently the patient's neurological findings are the same, and the psychiatric condition is within normal limits. CT was carried out twice, and both times showed cerebellar vermian atrophy.

Heath *et al* (1979) found CT scan abnormalities in 50% of 264 patients with functional psychosis, 42 (32%) of whom had cerebellar vermian atrophy. Nasrallah *et al* (1981) reported 43 schizophrenic and 15 manic patients in whom CT findings were consistent with cerebellar atrophy. The main function of the cerebellum is thought to be largely motor, and especially related to co-ordination, tonus, and balance, but some of the clinical and neurophysiological studies revealed new aspects of the cerebellum in relation to autonomic, limbic, and higher cortical systems (Hamilton *et al*, 1983). Wexler (1980) pointed to right hemispheric dysfunction in manic depressive psychosis and left hemispheric dysfunction in schizophrenic psychosis.

We conclude that there is probably a sub-group of schizophrenic patients in which the symptomatology could be related to structural brain lesions, which is also true for bipolar affective disorder.

Book Index Reviews

SIR: Book reviews rarely contain a reference to the index. Of the 137 books considered in Vol. **150** (January–June 1987) of the *Journal*, 9 indexes received some comment. Chick (p. 419), Jacoby (p. 421) and Smith (p. 134) used such expressions as "well-indexed", "comprehensive" and "excellent". Greer (p. 280) noted that "the omission of an index is a disadvantage", Kerr's "minor reservations relate(d) to the lack of an index" (p. 293), Rachman (p. 420) commented that "as there is no author index it was necessary to make a count", and Yach (p. 890) stated that "the index is somewhat rudimentary". Mayou (p. 573) "had to work hard turning from chapter to chapter and making the maximum use of the index". Wilkinson (p. 281), reviewing *Behaviour Therapy in Primary Care: A Practical Guide*, asks if "it is significant that the index contains no reference to illness, mental disorder, psychiatrist or psychiatry?"

With regard to the other 128 books, presumably some have adequate indexes, and some not. Is this information not worth recording by reviewers, especially if the book might be used for reference purposes?

A HUNDRED YEARS AGO

The report of the Superintendent of the Richmond District Lunatic Asylum reveals an almost incredible condition of things. "The sanitary state of the institution is deplorable. The waterclosets throughout are in a sad state. In the North (male) House there are in one group of wards no waterclosets whatever that are accessible for day use, and the only accommodation for 120 men is one earth chair." Under such circumstances, it is not surprising to find that out of an average population of 1076 as many as 117 were under hospital treatment for diarrhoea and dysentery during the year, or to find that these diseases caused twenty-two deaths in the same period; while for the past ten years they have caused an average of twenty-six deaths annually. "Erysipelas is rarely absent from the house, and in some years has caused a considerable number of deaths." This state of things demands remedy, and the newly appointed superintendent deserves every support in his attempt to put matters on a satisfactory footing. The percentage of deaths on the daily average numbers was 14.8, and that of recoveries on admission was 30.

Books Reconsidered

The Ego and the Mechanisms of Defence: Anna Freud*

This book was first published in English in 1937. In science fifty years is a long time, longer even than in politics, yet I can recommend psychiatrists to read this traditional psychoanalytic text for many reasons.

In the first place, for sentimental reasons. Anna Freud, daughter of the Master, is no ordinary analyst. Furthermore, her real contribution to psychoanalysis lay in her elucidation of the defences and in the very necessary extension of the work to children. Freudian developmental theory was largely retrospective and inferential, so that the work of Anna Freud was particularly valuable. This book is concerned with both these aspects of her work.

Another reason for reading this book is that the simplicity of the style and the immediacy of the clinical material give a powerful impression of the real nature of defence mechanisms. It is a pleasure to realise that subtle and rich descriptions of largely unconscious mental events can be described without jargon in clear, ordinary, yet striking language. Every psychologist or psychiatrist who has failed to resist the temptation to yield to jargon, however learned, in his reports or papers should read this book.

The content of the book, in my view, is still valuable. It sets out clearly the main defence mechanisms and is richly illustrated with clinical material. I know of no better guide to these unconscious processes. At this juncture, however, I can hear readers' objections that surely Freudian defences are old hat, that psychoanalysis has moved on, that modern analysts and psychiatry in general has outgrown the model of the mind implicit in the notion of defences.

This view of defences is, I think, mistaken. Thus, experimental psychology, which has always been so strongly opposed to psychoanalytic ideas, has recently become interested in unconscious processing (of information rather than affect), and concomitantly studies of subliminal perception are now more respectable in departments of psychology and there is a considerable body of experimental work relevant to defence mechanisms. I think this experimental evidence is important because it substantiates the psychoanalytic concept of defences.

Defences, given that they can be substantiated, are important for a variety of reasons. Firstly, for eclectic psychiatrists and psychologists they give valuable insights into behaviour. Notions such as denial and reaction formation are useful in unravelling presenting symptoms. Repression, too, is widely used even by workers who would refuse validity to anything psychoanalytic.

Furthermore, they are powerful in understanding complex attitudes and viewpoints in society, ones which often desperately require change. Thus to conceive of racism as projection helps us understand its protagonists and suggests methods of alteration. The violence of anti-vivisectionists, for example, and of football crowds, when seen as displacement becomes less strange. The savagery of those in favour of fierce punishment for sexual offenders and murderers, and the reaction-formation of those troubled by such conflicts, again makes sense.

Defence mechanisms, even for those who are cautious in accepting the concepts of psychoanalysis, have powerful explanatory force; they may be among the most long-lasting and useful ideas in psychoanalysis. Their lucid and elegant explication by Anna Freud seems to me well worthy of reading; this is a classic text.

Book Reviews

Editor: Sidney Crown

Suicide Risk: The Formulation of Clinical Judgement. By John T. Maltsberger. New York: New York University Press. 1986. Pp 174. $32.00.

The bibliography in this book is far longer than the index and contains in excess of 150 quoted publications. This might not seem out of the ordinary except that these include Jones on von Kleists' suicide, Seneca's *Lucillium Epistolae Morales*, Williams' *A Streetcar Named Desire*, Goethe's *The Sorrows of Young Werther*, and Asberg on 5-HIAA in the cerebrospinal fluid. This book beckons to be read, and the reader will not be disappointed. It is short and to the point, containing many illuminating and resourceful references well-rooted in literature, history, psychoanalysis, and general human experience.

So often American authors use a language tantalisingly reminiscent of English but startlingly incomprehensible. This is also unfortunately true of many psychoanalytic tracts closer to home. However, this book admirably avoids these pitfalls and is clear and straightforward. It is divided into 5 sections with a particularly entertaining and comprehensive excursion through the vulnerability to suicide (and it is possible to write in an entertaining manner about such a subject while never being light-hearted or frivolous). The other sections include the suicide crisis, recognising the suicidal patient, the formulation of suicide risk, and the pitfalls in estimating suicide danger.

The author proves most illuminating when highlighting the basic psychodynamic elements of vulnerability to suicide and the suicide crisis itself, as illustrated by "poor Blanche DuBois who in order to maintain her mental balance had always depended on the kindness of strangers" or in patients who lose their equilibrium when their idealisation of a leader is interfered with, such as in the case of Albert Joffe, a devoted communist who before committing suicide wrote to Trotsky when Stalin excluded him from the party, "... that is why it is time to put an end to my life... I cannot go along with the state of affairs where the party tolerates in silence your [Trotskys'] exclusion".

Perhaps the weakest area in the book is the final chapter, entitled 'Pitfalls in estimating suicide danger', which leaves one feeling somewhat frustrated by the author's attempt to place the unsuccessfully prevented suicide firmly at the feet of the professionals who are unable or unwilling to fulfil his rigorous criteria for a full psychodynamic formulation. Maltsberger alludes to the psychoanalytic and other therapeutic treatment strategies which would be introduced once this assessment has taken place: "formulation is the basis as well of intelligent psychoanalytic psychotherapy of suicidal patients, but these matters are outside the scope of this book". I suspect that a book covering these aspects would be a rather different kettle of fish. In addition, if it contained controlled outcome studies of such psychoanalytic treatments it would also be very short.

Nevertheless, these are relatively minor quibbles in what is an intellectually satisfying and very readable tome. I recommend it most highly to psychiatric trainees and general psychiatrists alike, although I suspect that the majority of doctors in casualty departments who are in the front line of the initial assessment of suicide risk would find it a rather daunting prospect. The relatively high price may put it out of the reach of people who might wish to read it at their leisure.

David Roy, *Consultant Psychiatrist, Goodmayes Hospital, Essex*

Interventions for Children of Divorce: Custody, Access, and Psychotherapy. By William F. Hodges. Chichester: John Wiley & Sons. 1986. Pp 374. £38.50.

This book aims to provide principles and guidelines for professionals working with children of divorce. The author has reviewed a large number of studies, but he points out that these are mostly descriptive and largely methodologically inadequate. However, the intervention strategies are clearly illustrated with examples, and these provide a valuable resource.

The impact of divorce on children is different depending on the age of the child. Hodges argues that we need to consider the characteristics of the child and their circumstances in order to establish what one would expect the child to understand and cope with. The theoretical basis of this work is developmental, and strongly based in object relations and Piagetion theory. Within this model the impact and long-term adjustment to divorce is considered.

There are chapters on medication, custody, visitation, and single parenthood as any clinical intervention should be placed in the context of the effects of different ways families reach their present status. The chapter on mediation is particularly important, as the evidence reviewed suggests that it is superior to court-resolved battles for all concerned. It is also argued that whatever post-divorce arrangements are made for children should be monitored and evaluated. With the high rate of remarriage the author has also reviewed work in this area, as clinicians often find themselves working with such families.

The second half of the book presents various models of intervention, including individual, group, and family therapy. Each approach is carefully considered and illustrated. At the end of the book Hodges provides a list of things that are not known and need to be known when helping children of divorce: there are thus plenty of suggestions for future research.

This book is well written and easy to use as a reference book – in view of the price this seems the most likely use. The fact that the research and practices reported are from America should not deter the British reader.

NIGEL BEAIL, *Senior Clinical Psychologist, Princess Royal Community Health Centre, Huddersfield*

Attempted Suicide: A Practical Guide to its Nature and Management (2nd ed). By KEITH HAWTON and JOSE CATALAN. Oxford: Oxford University Press. 1987. Pp 211. £12.50.

The second edition of this readable book is a little larger than the first. Its main format remains the same, and it is still the most useful basic text on 'attempted suicide' which is currently available. It is valuable at several levels, from a basic guide to practical management to a good summary of recent research work.

The new additions to the text reflect various recent changes in the clinical scene. Problems concerning unemployment, child abuse, adolescence, the role of psychotropic drug prescription, and up-to-date epidemiological findings are discussed in detail. The new DHSS guidelines on the management of deliberate self-harm are also mentioned, although it would have been useful to see them in their entirety. One omission concerns the recommendations that multidisciplinary standing committees should be established in each major clinical centre, charged with the tasks of monitoring standards of care and establishing codes of clinical practice, as well as methods of education and stimulating research. One wonders how widely this idea has been implemented throughout the country.

The book closes with consideration of the way forward and the many problems which beset primary prevention of 'attempted suicide'. It is indeed a source of disappointment that no research has yet shown any form of intervention to be effective in reducing repetition, and we are still in the early stages of identifying key issues in primary prevention of 'attempted suicide'. The exhausted casualty officer, facing yet another overdose patient, may still feel justified in believing that punitive stomach washouts could be effective as a way of preventing further repetition. In due course further enquiry will surely prove him wrong, and any aspiring researcher will find within this book many good ideas which deserve further exploration.

H. G. MORGAN, *Professor of Mental Health, University of Bristol*

In-Patient Psychiatry: Diagnosis and Treatment (2nd edition). Edited by LLOYD I. SEDERER. London: Williams & Wilkins. 1986. Pp 399. £45.00.

At a time when community psychiatry is fashionable it is curiously anachronistic to find a book which is almost entirely devoted to in-patient psychiatry. Yet even day-patient care receives only a brief comment here. The narrow focus does enable certain aspects of in-patient care to be discussed in more detail than is found in general psychiatric textbooks, but the multi-author nature of the book has resulted in a considerable amount of repetition. Young psychiatric trainees are often puzzled by what actually happens in a psychiatric ward and may be uncertain about how they should spend the individual time that they have with their patients, what community and staff meetings are about, and what the aims of in-patient group psychotherapy should be. Some attempt is made here to provide the psychiatrist in training with advice and clear guidelines, and the chapters devoted to group therapy, the therapeutic milieu, and the family are particularly well-written.

Unfortunately, much of the detailed factual information one would also expect to find in such a text is only sketchily presented, and there is much that British psychiatrists would take issue with; for example, the chapter on schizophrenia uncritically presents the views of such workers as Wynne and Singer, and is heavily biased towards psychotherapeutic management. Somewhat paradoxically, another chapter, devoted to the use of the laboratory, dogmatically recommends a number of "diagnostic" biochemical tests such as the dexamethasone suppression test, again without discussing any of the controversy surrounding their use. Considering that the book is dealing with in-patient treatment, ECT is dealt with inadequately and cognitive therapy only briefly mentioned. One is left to wonder whether this is to be thought of exclusively as an out-patient technique! The chapter on alcoholism fails to discuss aims other than abstinence in any depth, and the drug addictions are notable by their absence altogether.

Overall, the book would be of limited value to those preparing for the membership examination, but the sections dealing with interpersonal and social aspects of in-patient care probably make it a worthwhile addition to a psychiatric library.

LINDA GASK, *Research Fellow, University Hospital of South Manchester*

Psychotherapy and the lonely patient. Edited by SAMUEL M. NATALE. New York: The Haworth Press. 1986. Pp 120. £19.95.

I would not recommend this multi-author book. It contains eight papers on the title subject, ranging from an intellectually flabby meditation on the relationship between religion and loneliness (Palontzian and Janigian) to an extremely sophisticated analysis of a therapist's errors in two sessions with a rather schizoid patient who was incidentally lonely, i.e. unable to make use of the objects in his environment.

There is no conceptual or editorial unity between the various papers and their approaches (cognitive, pastoral, theological, and dynamic, among others). There is therefore no consistent argument as to the status of 'loneliness', either as a primary or as a secondary problem, nor is there a consistent view as to whether it is an entity to be treated in its own right or as a management problem. In the two papers which present clinical material in any depth (Gerardi, and Richmond & Picken), the patients' loneliness derives for the most part from the denial of aspects of the self (rage, envy, and depression) which precludes contact with others in relation to whom they might experience them. In those patients where cultural alienation or social disruption (divorce or retirement, for instance) present management or counselling problems, there is no suggestion as to the extent to which psychopathology might have prevented the patients from making their own initiatives, nor as to how to understand and meet resistance to well-intentioned, commonsensical advice.

I am afraid that I find nothing in this book to advance my ideas as to how to help the many patients in my own practice who suffer from loneliness either as a result of their pathology or because of their extreme isolation.

R. R. N. CARVALHO, *Consultant Psychotherapist, St Mary's Hospital, London*

Medicine and the Behavioural Sciences: An Introduction for Students of the Health and Allied Professions. By MICHAEL PRITCHARD. London: Edward Arnold. 1986. Pp 352. £19.95.

In recent years the introduction of the behavioural sciences into the curriculum of medical education, as well as similar developments in allied health professions, has predictably led to the publication of numerous books in this area. Most of these examine the contribution of either psychology or sociology to medicine, and there are many fine examples of this kind of book. Michael Pritchard's book, however, is rather different on several grounds. Firstly, he is a doctor, and he impressively demonstrates that it is possible to bridge the contrasting worlds of medicine and the behavioural sciences. Secondly, he attempts to present both psychology and sociology in an integrated fashion, although psychology takes up the lion's share of the twenty chapters. The third unusual feature of the book is its structure.

Part 1 includes a general introduction to the behavioural sciences and an overview of psychology and sociology. Pritchard chooses to structure the next four parts according to what he regards as "four basic and integrative psychosocial perspectives". In Part 2 he presents the 'analytical/reductionist' perspective. Here he examines familiar psychological processes such as perception, learning, and motivation. There is also one sociological chapter, entitled "Social structure and the individual". Part 3 explores the 'developmental/historical' perspective, covering both individual and societal change. Part 4 addresses the issue of differences in behaviour both between individuals and between societies. There is a brief examination of social anthropology and separate chapters on personality and intelligence. Part 5 is entitled "Interactional perspective", and focuses on social psychology and clinical aspects of social interaction. Part 6 is a single chapter on "Psychosocial aspects of disease". Although this brief chapter by no means does justice to the considerable volume of research in this area, in fairness to Pritchard it should be pointed out that throughout the book he refers to clinical aspects of each subject.

I didn't find it easy to chart my way through Pritchard's unfamiliar framework, but perhaps the non-behavioural scientist would not be handicapped by this kind of limiting structural expectation. There is certainly a lot of interesting material which could be valuable to the health professional. I have some reservations, however, mainly about potential readership. There are undoubtedly many students and colleagues in the health professions who are thirsty for knowledge about psychosocial aspects of health, and I would happily recommend this book to them. For the majority who just want a basic introduction, however, I don't think this will be their cup of tea: it is likely to be too technical and in-depth for their tastes, and it lacks a central clinical focus. In fact, I regard the title as misleading. The book is basically about the behavioural sciences, and has little to do with medicine. I strongly agree with Pritchard's expressed aim to stretch readers beyond the obviously clinically relevant, but I suspect you have to first tempt them with what they are really interested in, namely illness and ill people.

ERIC BUTTON, *Lecturer in Clinical Psychology, University of Southampton*

Community Psychiatric Nursing: A Social Perspective. By SUE SIMMONS and CHARLIE BROOKER. London: William Heinemann. 1986. Pp 196. £8.95.

In a recent radio programme about medical matters an item of research, carried out by nurses, was presented. A video had been made of the research findings "rather than present them in a learned journal". "Nurses do not read such journals", was the rationale, and one wonders how that contributes to the frustrations and dissatisfactions so common in the profession and how the academic and intellectual potential of able nurses is realised.

This book is evidence that a contrary view has voice in the CPN profession at least. It is well written, well situated in a real practical world, and firmly based on research evidence which it reports cogently and coherently. It unashamedly claims a real place for CPNs in the development of new mental health services and does not waffle about sharing tasks and blurring boundaries with other disciplines. As such, the authors may have trodden on some toes, especially in Social Service departments!

However, it backs up its claim to an exciting future for CPN services by describing the role of the CPN from a wide variety of standpoints – individual case work, relationship with social networks, and service and organisational issues. It begins from the premise that socio-economic and other environmental factors are important to the development of mental ill health and sets the scene well for a readership inexperienced in these areas.

It is good to see a book by nurses and for nurses, which is prepared to embrace a wide range of mental health literature and interpret it so clearly. A must for all hospital libraries.

GILLIAN WALDRON, *Consultant Psychiatrist, Tower Hamlets Health Authority, London*

The Psychiatric Implications of Menstruation. Edited by JUDITH GOLD. Cambridge University Press. 1986. Pp 102. £15.00.

This fascinating little book, which forms a volume in the series *Progress in Psychiatry,* is made up of a series of short essays on the many aspects of menstruation and its disorders. The result is an immensely enjoyable book which is both informative and easy to read. The many contributors include psychiatrists, psychologists, and gynaecologists. The book begins with a valuable review of the many types of premenstrual depressions and discusses interactions that depressive illness can have in relation to menstruation. As a gynaecologist, I found this chapter of great value and I know that the discussion of this subject will be of great help to me in clinical practice. There follows a fascinating review by Ellisa Benedek of the use of premenstrual syndrome as a defence in law; this chapter includes descriptions of all cases where such a defence has been tested, both in the USA and in Britain.

The problem of stress in university students and its effect on menstruation is discussed, together with the role of examinations and athletics in the production of menstrual disorders.

Anorexia nervosa and its effects on menstruation is also included and the physical aspects of the problem are discussed, but I would have liked to have seen further discussions concerning the endocrine aspects of this disorder than were presented in this chapter.

A chapter entitled "Grief process after pregnancy loss", by Elizabeth Herz, was an extremely welcome inclusion as this section covered the problem of miscarriage and not stillbirth. Early pregnancy loss is rarely reviewed in standard textbooks, and such a good review of the subject was a pleasure to read. The book concludes with two chapters covering the psychological sequelae of infertility and the menopause. The latter reviews the many myths that abound concerning the end of menstruation and does much to sort fact from fiction in this subject.

Overall this is a useful little book from which I have learnt a great deal. It covers the interactive area between psychiatry and gynaecology, about which there is often little understanding and frequently much confusion. By reading this book I have become much better informed. I would recommend it most strongly not only to psychiatrists, at whom it is primarily aimed, but also to gynaecologists.

ANNE M. JEQUIER, *Senior Lecturer/Honorary Consultant in Obstetrics and Gynaecology, Queen's Medical Centre, Nottingham*

Premenstrual Syndrome: Current Findings and Future Directions. Edited by HOWARD J. OSOFSKY and SUSAN J. BLUEMENTHAL. Cambridge: Cambridge University Press. 1986. Pp 95. £15.00.

The premenstrual syndrome is a difficult subject both to understand and to treat. Its aetiology is not defined, its pathophysiological basis is not understood, and therefore its treatment must, to some extent at least, only be empirical. Indeed, there are some who do not think that the syndrome even exists. However, there cannot be many gynaecologists who face the apparently increasingly frequent problem in the clinics that would agree.

This book, which forms a volume in the *Progress in Psychiatry* series, addresses the whole problem of the premenstrual syndrome and the result is a most informative and useful review. It begins with an overview of the affective disorders and their relationship to premenstrual depression. The close association between the two is described, and the interaction between depressive illness and the premenstrual syndrome outlined in a most helpful way.

There follows an interesting chapter concerning the biology of premenstrual changes, which consists of a careful review of the 'hard' evidence that hormonal changes induce premenstrual syndrome. It would appear that the monamine oxidases may be of great importance.

A chapter concerned with menstrually related mood disorders includes useful methodology of visual analogue scales and other self-rating schemes. The authors also discuss in detail how premenstrual depression may be mimicked by many of the affective disorders that can occur episodically. The interaction between affective disorders and premenstrual depression is further explored. As a gynaecologist, I am sure that my management of patients who complain of menstrually-related depression will be considerably improved by my reading this chapter.

The evaluation of premenstrual syndrome, together with general advice on treatment of less severe forms of the disease, is clearly described in a good and well-balanced central chapter. The management of more severe forms of the syndrome is also fully reviewed, together with the treatment of any other co-existing psychiatric disease. It is pointed out that few controlled studies are available, and that there is scant evidence for the existence of any therapy of proven value for premenstrual disease. The volume concludes with a chapter concerned with cognitive approaches to the treatment of premenstrual depression and a chapter on research techniques used to study the premenstrual syndrome.

This is a very interesting and valuable little book. Although it is written exclusively by psychiatrists, it will be of considerable value to gynaecologists who probably see as much of this disorder as anyone. It was a pleasure to read such a concise and objective review of this difficult problem.

ANNE M. JEQUIER, *Senior Lecturer/Honorary Consultant in Obstetrics and Gynaecology, Queen's Medical Centre, Nottingham*

Masters of Madness: Social Origins of the American Psychiatric Profession. By CONSTANCE M. MCGOVERN. Hanover, NH: University Press of New England. 1986. Pp 262. £18.00.

Reading this book I experienced a strange feeling of déjà vu: it all seemed so familiar. And then it dawned on me that this was because the history of American psychiatry is essentially the history of English psychiatry told with an American accent.

The Association of Medical Officers of Asylums and Hospitals for the Insane was founded in England in 1841, whereas the American analogue, the Association of Medical Superintendents of American Institutions for the Insane (now the American Psychiatric Association), was founded three years later in 1844. The origins of these associations in both countries lay in the expressed wish of well-intentioned men to pool their experience with the earnest desire of improving the treatment of the insane.

There were differences in emphasis, of course, but the rise and the fall of the asylum systems in England and America ran roughly parallel courses, although it is in the context of the demise that the closest approximation can be seen. What is most remarkable is the sharp division of opinion which has arisen in both countries as to the desirability of closing the mental hospitals.

This division could not be better illustrated than in the quotations given at the beginning of Chapter 7, which are the declared views of two Presidents of the American Psychiatric Association. In 1958, Harry C. Soloman opined, "I do not see how any reasonable objective view of our mental hospitals can fail to conclude that they are bankrupt beyond remedy . . . [they] should be liquidated as rapidly as can be done". However, in 1984 John A. Talbott had occasion to write, "Our public facilities are deteriorating physically, clinically, and economically: our chronically ill are either 'transinstitutionalised' to nursing homes or deinstitutionalised to our cities' streets".

It seems a pity that this most readable and informative book should be marred by occasional lapses in scholarship. For example, there is not and never has been a "British Association of Medical Officers of Lunatic Asylums". Again, the author alleges that at the trial of Daniel M'Naghten (*sic*) the court decided that a person was insane if he could not distinguish right from wrong. The court decided no such thing; the so-called right/wrong test was incorporated in the McNaughton Rules which were formulated after the trial.

HENRY R. ROLLIN, *Emeritus Consultant, Horton Hospital, Epsom*

What is Epilepsy? The Clinical and Scientific Basis of Epilepsy. Edited by M. R. TRIMBLE and E. H. REYNOLDS, Edinburgh: Churchill Livingstone. 1986. Pp 350. £40.00.

There have been many books on epilepsy in recent years, including several involving one or other of the editors of this book. It is easy to justify the production of these volumes on the basis that epilepsy is a common problem, but non-specialists may be forgiven for wondering whether there is really sufficient new information to require the use of so much paper. The present volume has arisen from the symposium which took place in July 1985, "To review the present state of knowledge and to discuss its relationship to the larger, central question; what is epilepsy?". The latter is a question of philosophical interest, but is not of much importance in clinical practice, in which an entirely empirical approach is taken to all such questions. This book has, in fact, much to commend it. It consists of 24 review chapters, each well-written and representing an authoritative view. Even hoary old classics such as the classification of seizure disorders make interesting reading. The scope of the book ranges from a historical introduction, through discussions of problems of epilepsy in children, differential diagnosis from other paroxysmal neurological disorders, EEG, seizure monitoring and depth electrode studies, hysterical seizures, and other interactions of psychiatry with epilepsy, to a number of concluding chapters on monkey models of epilepsy and new advances in pharmacology, largely of an experimental nature. Thus, there is something of interest not only for clinicians, including paediatricians, psychiatrists and neurologists, but also for the basic scientists. Each chapter is complete in itself and the reader is spared transcripts of the discussions that no doubt occurred at the meeting until the last two chapters. I recommend that the reader delete these from his copy: there really cannot be any point in printing sentences such as "I think that is an important point... it is a very important issue". The book concludes with a brief index, but unfortunately this is woefully inadequate. In view of the discrete nature of each individual chapter this makes it extremely difficult for the reader to find particular subjects. Naturally, many are covered in different chapters in different ways, and the only thing to do is to read through the whole book! Nonetheless, this book is generally more useful, more readable, and better written than other recent volumes on epilepsy and it deserves to be widely read.

MICHAEL SWASH, *Consultant Neurologist, London Hospital*

Liaison Psychiatry: Mental Health Problems in the General Hospital. By JOAN GOMEZ. Beckenham: Croom Helm. 1987. Pp 276. £22.50 (hb), £10.95 (pb).

This textbook of general hospital psychiatry is an introductory one for trainee psychiatrists, medical students, and general physicians and surgeons. After four general chapters each area of medicine is covered in varying degrees of detail.

Unfortunately, the first chapter may alienate physicians and surgeons, especially those who do have a positive attitude to psychiatry and prescribe psychotropics in adequate doses. The medical student and trainee psychiatrist may be put off by the daunting list of 24 tasks that the liaison psychiatrist "could and should do", and the established psychiatrist may be irritated because this book teaches that psychiatry is a 'soft' subject (even though the author emphasises the need to establish 'hard' data), that the psychiatrist is the one who must find out why a patient harmed himself, and that memory impairment is a feature of depression. This is a pity, because the book does contain some useful advice arising out of the author's extensive clinical experience.

By repeatedly emphasising the role of the liaison psychiatrist (he can help all concerned in the care of the dying, yet has no panacea) Gomez gives the impression of a special area of clinical practice rather than a set of skills that all doctors should adopt. The assessment of patients is not sufficiently direct and the psychological treatments not presented in sufficient detail for physicians to use this as a handbook. The critical trainee physician and psychiatrist will be irked by the lack of research data, and references are quoted in a rather haphazard way. The prevalence of depression among patients prior to hysterectomy, in neurological units, and in those with irritable bowel syndrome is dealt with very superficially and a book of this nature requires more than a short paragraph for subjects such as hypochondriasis, and the relationship between life events, depression, and physical illness.

Some may find this a useful text, but the rapid development of research findings relating physical and psychiatric disease surely merits a more exciting textbook on this subject.

FRANCIS CREED, *Senior Lecturer and Honorary Consultant Psychiatrist, Manchester Royal Infirmary*

Treatment of Multiple Personality Disorder. Edited by BENNETT C. BRAUN. Washington: American Psychiatric Press. 1986. Pp 206. $17.50.

This book is a collection of chapters by different authors, devoted mainly to the treatment and prognosis of multiple personality disorder (MPD). It is evident that most of the authors have worked together and share the same views of the disorder, which they have conveniently categorised. They share a model of the aetiology of MPD which includes: (a) an inborn capacity to dissociate, usually identified by excellent response to hypnosis; (b) repeated exposure to an inconsistently stressful environment in which the subject has separated the good and the bad into two or more historical chains; and (c) an overwhelming traumatic episode to a vulnerable person which induces dissociation into the previously constructed partial memory and personality. Thirteen basic issues in psychotherapy for MPD are identified: developing trust; making and sharing the diagnosis: communicating with each personality state; contracting agreements about the limits of patient behaviour; gathering history; working with each personality state's problems; undertaking special procedures, such as hypnosis, which have been found particularly helpful in the treatment of MPD; developing communications between the different subpersonalities; achieving resolution and integration; developing new behaviours and coping skills; using social support systems; consolidating gains; and follow-up.

The accent is on individual psychotherapy, but there is also a chapter on the use of group psychotherapy as an adjunct to individual work, the development of social support systems, and the use of drugs. Different subpersonalities in the same individual react differently to medication. This is a fascinating area, which if extended could complement the classic study of 'the pharmacology of placebo'. There is a chapter on the diagnosis, commentary, treatments, and follow-up of 52 patients with MPD. The average number of personalities is 15.4, the commonest number being 5 personalities and the maximum in this study being 110 sub-personalities in one individual. The average period of treatment was 22 months. Relapse was much commoner in patients with 18 or more personalities, in whom 60% had partial or complete relapse. Patients with 17 or fewer personalities had an 8% relapse rate.

In North America, the diagnosis has become increasingly common – even in 1980 there were only 200 cases recorded in the literature, but since then there have been many series published, some of them in the hundreds. It is difficult to know how much of this increase presents a true increase in the affected population and how much is due to an increasing awareness among psychiatrists resulting in more accurate diagnosis. It may also be possible that now that the diagnosis has become fashionable, it may be over-diagnosed. Patients may also have learned to conceptualise their problems in ways that attract professional and lay interest. There seems to be an important relationship between child abuse and the later development of MPD, and it is of great interest that the increase in the diagnosis of MPD parallels the increased awareness of child abuse which has been a feature of the past 10 years. Many MPD patients have been previously diagnosed as borderline personality, normally considered difficult to help psychotherapeutically in contrast to the excellent results described in the volume under review. It may be that the authors' cases were easier ones, or it could be that the diagnosis of MPD and the specific psychotherapeutic strategies used with these patients is a more helpful way of viewing some cases of borderline personality.

Where there are very sudden changes in mood of patients with a 'personality disorder' and the appearance of 'psychotic' phenomena in patients whom we are fairly certain are not psychotic, we may find with further enquiry that the phenomena may be more readily understood in terms of MPD. It remains to be seen whether the experience of this syndrome in the UK will compare to North America, but if it does this collection of essays will be a helpful guide in its diagnosis and treatment.

OSCAR HILL, *Consultant Psychiatrist, Middlesex Hospital, London*

Handbook of Studies on Schizophrenia. Part I: Epidemiology, Aetiology and Clinical Features. Part II: Management and Research. Edited by GRAHAM D. BURROWS, TREVOR R. NORMAN and GERTRUDE RUBINSTEIN. Amsterdam: Elsevier Biomedical Press. 1986. Part I: Pp 246. $72.25. Dfl. 195.00. Part II: Pp 313. $250.00.

These two thin volumes are not conference proceedings, but contain a collection of invited contributions from authors from a number of countries, including Australia. Every conceivable aspect of schizophrenia is covered; there is an emphasis on biological aspects, but chapters on social and family factors, patient services, and even schizophrenic art are included. The standard in general is very high. Many of the chapters provide balanced, detailed, and up-to-date reviews which are exhaustively referenced. A minority are less than comprehensive, and one or two authors seem content to review mainly their own work. Most impressive are the ten or so chapters relating to aetiology and pathogenesis, where the cover is authoritative. The chapters on pharmacotherapy are wide ranging and informative, and those on family therapy and psychotherapy are clear and even-handed. Unfortunately, there is a relative neglect of the clinical features of schizophrenia: the three chapters devoted to this are individually of a high standard, but several important issues are alluded to rather than examined in detail. However, specialised topics such as schizophrenia in epilepsy, organic states, and the puerperium are given a great deal of attention.

This handbook is of general interest; it provides readable accounts of many important topics, and would thus make a valuable addition to a psychiatric library. It would also be of great assistance to anyone with research interests in schizophrenia. Finally, to those, like the reviewer, who have had to teach on schizophrenia at a postgraduate level it is probably indispensible.

P. J. MCKENNA, *Lecturer in Psychiatry, High Royds Hospital, West Yorkshire*

The Sociology of Mental Disorders (2nd ed.). By WILLIAM W. EATON. New York: Praeger. 1986. Pp 281.

Eaton, who is a psychiatric epidemiologist at John Hopkins University, has responded to the success of the first edition of his sociological primer in psychiatry by incorporating a number of important recent developments. These include DSM-III and the NIMH Epidemiologic Catchment Area Program; more surprisingly, he has added three literary first-person accounts of mental disorder, including an extract from Sylvia Plath's *The Bell Jar*. The social approach here begins by separating "bizarre behaviours" from the rest of human life, and then considering them as either disease or deviance. This is followed by considering the social epidemiology of mental disorders, in which it is rather surprising to find demoralisation as a major category. The remaining sections deal with social psychology, the family, collective behaviour, organisation of treatment, socio-economic stratification, and mental disorder in the modern world (with emphasis on the views of Marcuse, but no mention of Basaglia).

The limitations of present-day sociology in confronting the issue of psychiatric disorder are, on the whole, frankly acknowledged here. For instance, the conceptualisation of social supports and life events stressors is not complete because of the failure to separate the two clearly; there is an absence of intensive population-based family studies; and data on mental disorder have not yet been brought into a comprehensive theory of ethnic and class stratification. On the other hand, some yawning gaps are skated over – family theories of the aetiology of schizophrenia are discussed without reference to either the absence of control samples or the excess of perinatal damage in those who later become ill.

This is generally a very lucid and jargon-free account of the relevance of sociology to psychiatry, which is likely to be useful to trainees in any of the mental health professions, if supplemented by, for instance, *Ideas on Institutions.* The focus, though, does tend to be strongly more American, and Europeans will be surprised to read that "The role of left-fielder entails expectations about fielding fly balls", as they are unlikely to have any such expectations at all.

HUGH FREEMAN, *Editor, British Journal of Psychiatry*

Treatment of Affective Disorders in the Elderly. Edited by CHARLES A. SHAMOIAN. Cambridge: Cambridge University Press. 1986. Pp 84. $15.00.

There are two cuckoo eggs in this slim book; a survey of the dexamethasone suppression test and platelet monoamine oxidase in cognitive impairment and depression, and a retrospective case-note admission study examining the hypothesis that age of onset of depression is associated with increased risk of delusions, unconvincingly disclaiming referral artefact: both would have been better published (or not, perhaps) elsewhere. There are five better eggs, including a brief survey of controlled trials of antidepressant medication in elderly patients, a very useful review of the cardiovascular effects of tricyclic antidepressants, and a helpful synopsis of the pharmacological treatment of depression in patients with cardiovascular disease. The other reviews – of mood disorders in post-stroke patients, and of kidney function and lithium treatment in the elderly – are less useful, in that the former preaches to the converted, while the latter is rather sketchy. There is useful material in this book for those responsible for psychopharmacological treatment of the elderly in hospital.

A. J. D. MACDONALD, *Senior Lecturer in Psychogeriatrics, Hither Green Hospital, London*

Living with Teenagers. By MARTIN HERBERT. Oxford: Basil Blackwell. 1987. Pp 238. £6.95.

This is a sound guide to adolescence, primarily intended for parents and teachers, by an author who is well-informed and able to discuss the subject in a balanced, intelligible way. Herbert deals with the nature of adolescence, independence versus authority, emotional difficulties, anti-social behaviour, sexual activity, school and work, including school problems and unemployment, and ways of helping when problems arise. The author is a psychologist, and throughout the book there is a tendency towards the methods of clinical psychology – behavioural psychology, problem-solving techniques, and cognitive approaches; commendable, but rather dull and systematic, especially the various check-lists. However, social and psychodynamic aspects of adolescence are mentioned, and the book is enlivened by occasional cartoons reproduced from *Punch* and elsewhere. This is a steady, thorough and serious book and I would recommend it for a short-list of books on this theme for the general reader.

DEREK STEINBERG, *Consultant Psychiatrist, Bethlem Royal Hospital, Kent*

Epilepsy in Young People (Portsmouth Symposium, 1986). Edited by EUAN ROSS, DAVID CHADWICK and ROBERT CRAWFORD. Chichester: John Wiley. 1987. Pp 169. £21.95.

The editors present a sound and sensible guide to epilepsy in adolescents suitable for any in-coming houseman, even if the slightly patronising title suggests, rightly, that it is based on symposium proceedings. Chapters on pregnancy, when to start treatment, when to stop, and how to explain epilepsy to a child are particularly meritorious. A weakness is the lack of consideration of the management of behavioural problems associated with epilepsy, but there is a superb chapter by Gregory Stores on non-convulsive status epilepticus in childhood presenting with essentially behavioural manifestations. In the ensuing discussion, Michael Trimble includes the phenomena of psychotic patients with spike-wave discharges confined to the limbic system and scanty epileptic changes on surface electrodes. In the light of new investigative techniques discussed in the symposium, can we persuade the same team to tackle the vexed topic of prolonged states of coma, confusion, and catatonia in children?

E. M. R. CRITCHLEY, *Consultant Neurologist, Royal Preston Hospital, Lancs*

From Asthma to Thalassaemia: Medical Conditions in Childhood. Edited by SARAH CURTIS. London: British Agencies for Adoption and Fostering. 1986. Pp 159. £7.95.

This short book, designed for social workers and those involved in the adoption of children with medical conditions, has its main value in the list of references at the end of each chapter. Most of the introductions are too sketchy to be helpful. Exceptions to this are those on cardiac conditions and cerebral palsy, which could have been models for the other chapters. Conditions such as Huntingdon's chorea and schizophrenia sit rather uneasily alongside muscular dystrophy and malignant diseases. The general chapters were too general to make real connections with the more specialist chapters on particular diseases, and some of the advice and information seems to be distinctly old-fashioned. I cannot, therefore, recommend the book as a whole to social workers and others who seeks an easy guide to medical conditions in children placed for adoption. Perhaps such a book could be used for those who are likely to adopt children with medical needs, rather than for professionals; it might be a good source book for running groups of potential adopters. It suffers from breadth of coverage, and I think that most people who adopt children with particular needs would seek much more detailed information on a practical level about a particular condition from which the child they are adopting suffers. It is a constant complaint of parents with children with all kinds of medical and psychological disturbances that they are not well enough informed by the professionals. I think this book is only a very small step towards informing professionals about particular problems, and sadly I think therefore it is not the best source of information for the conditions covered.

LES SCARTH, *Consultant Psychiatrist, Royal Hospital for Sick Children, Edinburgh*

Post-Traumatic Stress Disorder in Children. Edited by SPENCER ETH and ROBERT S. PYNOOS. Cambridge: Cambridge University Press. 1986. Pp 186. £15.00.

The contributions in this book are based on 'first-generation' descriptive research relevant for the new DSM-III category of post-traumatic stress disorder as it applies to children. They outline children's responses to a variety of stresses which include witnessing of acts of violence (homicide, rape, suicidal acts), traumatic bereavements, childhood cancer, physical and sexual abuse, war and migration, group kidnaps, and natural disasters such as volcanic eruptions.

Some interesting observations are made which provide useful clinical insights. However, the diversity of situations addressed and the individuality of the approaches used to study them result in an unsatisfactory lack of cohesion, and the inclusion of children's responses to such varied traumas under the single category appears contrived. If a clear message emerges from this book, it is the need for further discriminating, clarifying work into the post-traumatic reactions of children.

ELENA GARRALDA, *Senior Lecturer in Child Psychiatry, University of Manchester*

The Psychoanalytic Study of the Child. Vol 41. Edited by ALBERT J. SOLNIT and PETER B. NEUBAUER. London: Yale University Press. 1987. Pp 667. £50.00.

This series has now reached its first volume in as many years, which would be testimony to its worth even if the list of distinguished contributors over the years (Anna Freud, Bowlby, Margaret Mahler and others) did not include many of the best-known names in the field of psychoanalysis and developmental psychology.

There are no names as familiar as these in volume 41, which continues the tradition of including a large number of contributions (28 chapters) by an even larger number of authors. The contributions are divided into five sections under the headings Psychoanalytic Theory, Trauma, Child Development (subdivided into childhood and adolescence), Clinical Contributions, and Applied Psychoanalysis. There is also a chapter on 'The executive functions of the ego', which is a wide-ranging discussion of psychodynamic approaches to the conceptual problems of free will and autonomy. Despite its title, much of the book is concerned with adult psychoanalysis, or with issues relevant to adult psychology.

A book such as this is one to be dipped into rather than read from cover to cover. However, the contents pages do not seem to offer much of immediate interest to the general reader, and indeed the language of the titles would deter many. Nathanson on 'The empathic wall and the ecology of affect' and a multi-authored chapter on 'Special solutions to phallic-aggressive conflicts in male twins' are cases in point. On further investigation the contributions range from thought-provoking (Edelson on 'Causal explanation in science and psychoanalysis') through workmanlike, but unexciting (Anthony's chapter on 'The contributions of child psychoanalysis to psychoanalysis', for example) to provocative (Abrams' chapter entitled 'Disposition and environment' rather mischievously shows how different psychoanalytic theories can explain the carefully researched observation that twins separated at birth turn out to be temperamentally very similar even when the nurturing families are very different).

What then might be the value of this collection to the general psychiatrist? Psychoanalysis both as a theoretical and practical discipline has contributed more to the day-to-day practice of psychiatry than is generally acknowledged, particularly to the general belief that any formulation of a psychiatric problem is incomplete without understanding of the patient's history, development and early relationships. This book is in the main concerned with the exploration and clarification of patterns as normal and abnormal development. There is also a great deal of interest to those with little interest in the practice of psychotherapy but who maintain an intelligent concern for art, philosophy, or science. It is a tribute to the editors that in the main the contributors to this volume follow the suggestion of one of the authors represented (Edelson): "Psychoanalysis is a body of knowledge that is important to a wider intellectual and scientific community than that comprised by psychoanalytic practitioners. In its documentation it should follow the scholarly practices, and accept the standards, of that community."

GRAEME MCGRATH, *Lecturer in Adult Psychiatry, University of Manchester*

Advances in Therapies for Children. By CHARLES E. SCHAEFER, HOWARD L. MILLMAN, STEVEN M. SICHEL and JANE R. ZWILLING. San Francisco: Jossey-Bass. 1986. Pp 450. £34.00.

If you want a quick, helpful and fairly current reference to specific treatment for a wide variety of child and adolescent disorders such as nightmares, shyness, temper tantrums, restlessness or overdependent relationships with adults, look no further. This is the latest volume in the series of reference books on treatment of emotional and behavioural problems in children and adolescents. Readers familiar with the earlier volumes will recognise the basic structure. There are six chapters devoted to classes of clinical problems, including neurotic behaviours, habit disorders, and disturbed relationships with children. Each has an introduction followed by sub-sections dealing with more specific clinical problems such as school phobia, temper tantrums, fire-setting, and social isolation, among many others. Every sub-section has an introduction followed by a brief but informative account of published reports describing different treatment techniques for the particular problem. These specially written accounts are the core of the book; they provide sufficient information to guide the implementation of treatment, and are accompanied by a commentary that draws out some of the important features of the treatment. The selections are unbounded by theoretical constraints – indeed, the eclecticism is intentional. Finally, each section ends with annotated references to yet other treatment approaches or to issues related to the same problem.

The authors give a number of reasons for eclecticism. One is in response to an increasingly widely recognised phenomenon in treatment: that treatment has to be specific to the problem; neither psychoanalysis on its own or behaviour therapy on its own will suffice to treat the diversity of child and adolescent problems. Instead, practitioners must be eclectic, chosing treatment to match problem and cicrumstances. Furthermore, recognising that treatment effects do not generalise, increased attention must be given to involving parents. Finally, they have been influenced by the trend towards community-based prevention and education. The selections reflect these views.

The danger of collections such as this is that they encourage technique-centered clinical practice. Although this has some uses, it also has many limitations. These dangers apart, this volume and its predecessors should be useful to trainees and others early in their careers. Experienced clinicians will also find it enormously helpful as a way of keeping up with current approaches to treatment. It is, after all, difficult to peruse the diversity of journals that publish treatment reports in order to keep up to date. With periodic updating this series will continue to provide an important service to clinicians. At this sort of price, however, it will be a candidate for departmental rather than individual budgets.

MICHAEL BERGER, *District Psychologist, St George's Hospital, London*

The Psychotic Core. By MICHAEL EIGEN. Northvale, NJ: Jason Aronson. 1986. Pp 387. $30.00.

Eigen's focus is not limited to those individuals who are psychiatrically diagnosed as psychotic or borderline. Rather, this book is a rich phenomenological and psychodynamic exploration of "the mad dimension of life", a discussion which has both breadth and depth. He argues that "overtly psychotic individuals make up a relatively small proportion of both the general and patient population, but psychotic attitudes and states can be components of a broad range of emotional states and mental disorders".

Drawing on a variety of analytic theorists' contributions, especially Bion, Eigen considers various dimensions of psychosis: hallucination, mindlessness, disturbances of boundaries, domination of mind by hate, and disturbances of epistemology, of knowing and the sense of knowing. Eigen demonstrates the links between these disturbances in overtly psychotic subjects and their more subtle manifestations in 'normal' life – that psychotic individuals are struggling with issues that concern us all, that are an inherent part of being alive, for example such as pain.

The psychotic hate which Eigen addresses is often directed not only against an external world perceived as threatening or ungiving, but also against the self, its needs, and its love because these are a source of pain. However, while hate is destructive, even more devastating in their anti-life aims are the self-erasing functions described by Bion, denoted by a minus sign: $-K$, $-L$, $-H$ refer to the psychotic individual's tendency to attack the linking activities of knowing, loving, and hating. Eigen gives descriptions of attempts to omnipotently annihilate emotional life in order to avoid emotional pain. For example, one patient spoke of a 'shredder' which operated to obliterate any emotional meaning that threatened to arise. She conveyed how therapy became the major source of pain in her life because if only she could obliterate the therapist she would not need to know how alone she felt: "she and shredder would live in peace".

Eigen argues that a sense of catastrophe may lie at the origin and core of mental life, in healthy development functioning as a signal to initiate urgent attempts to engage the caregiver. When catastrophe loses value as a signal and threatens to become the pervasive reality, the subject may adapt by various forms of blanking out, or mindlessness – much like some of the autistic phenomena described by Meltzer *et al* and Tustin.

Eigen argues that Freud's work was to "initiate the most detailed investigation in the history of Western thought into the way pleasure is substituted for pain". The study of psychosis further elaborates the link between madness and lies. The lies and mental trickery of psychosis are not limited to those who are psychiatrically diagnosed. For example, Eigen refers to a recent presidential election campaign in which the illusion of good feelings (represented by one candidate) was successfully presented as preferable to a focus on painful realities (represented by the other candidate).

Destructive though madness is for individuals and societies, Eigen doubts that it can ever be eliminated. He views madness and sanity as basic polarities which structure our existence, just as does the awareness of birth and death. Moreover, he concludes: "the horrific has its own beauty, its own ecstacy, and we ought not walk round it as if it were not there, no more than we should become one with it".

Along with James Grotstein, to whom the author refers, Eigen must certainly rank amongst the foremost of contemporary analytic therapists and theorists who are making significant steps in furthering our understanding of madness. Any clinician who has ever attempted to understand the thoughts and experiences of psychotic patients will find much that is illuminating and well described in this book.

PHIL MOLLON, *Regional Psychologist in Psychotherapy (Top Grade), Dryden Road Hospital, Newcastle-upon-Tyne*

The Language of Psychosis. By BENT ROSENBAUM and HARLY SONNE. New York: New York University Press. 1986. Pp 141. $32.00.

Any attempt to unscramble 'word-salads' and neologisms is to be welcomed. The authors, a psychiatrist and a linguist respectively, include many written and spoken examples of these fascinating phenomena. However, the very nature and content of the work, coupled with possible differences in Danish and North-American styles, may have resulted in quite large sections of textural incomprehensibility for the ordinary British psychiatric reader. Certain key words are indeed carefully defined, for example 'deixis', 'anaphoric', and 'transitivism', but their too frequent use represents a characteristic which, some may feel, obscures understanding of the authors' thesis, an extract of which follows:

"The binding arises by virtue of a systematic and structurally stable inscription of signifiers in a relatively ordered and logical form of text. The individual discursive register is where inscription takes place. It appears from the above that the unconscious is the most marked property and mode of operation of the discursive register. By this we do not mean that the discursive register has been fully described. This is not the case. Some of the other important functions and properties of the discursive register arise from the way in which the inscription of the discourse, for the most part, takes place."

Psychoanalytic terms and concepts are, as stated, certainly included and are alloyed with linguistics and semiotics.

HAROLD MAXWELL, *Consultant and Honorary Senior Lecturer in Psychotherapy, West Middlesex and Charing Cross Hospitals, London*

A Critical Dictionary of Jungian Analysis. By ANDREW SAMUELS, BANI SHORTER and FRED PLAUT. London: Routledge & Kegan Paul. 1986. Pp 170. £6.95.

In the introduction to the dictionary the joint authors' clearly stated task was an attempt to define, give the origins of, and trace the changing usage of terms used in analytical psychology. This is complemented by the inclusion of other psychological terminology, but particularly terms shared by psychoanalysts. There is an efficient system of cross-reference within the dictionary, and definitive comments by other authors are included. There is also an extensive bibliography. The authors acknowledge the influence of the two relatively recent publications of psychoanalytic dictionaries, written by Laplanche & Pontalis (1980) and Rycroft (1972), in making them aware of there being no such equivalent in analytical psychology.

Since Jung's death there has been an increasing interest in Jung's ideas and a broadening in the scope and terms of reference covered by post-Jungians. This "critical" dictionary was written to trace the evolution of definitions used in analytical psychology and as the basis for further discussion. Experienced practitioners will value the clarifications which can be used as the authors intended, namely as the focal point of discussions. For most other readers I think that this work is invaluable, not merely as a concise means of absorbing information, but as the stimulation to explore many of the concepts in much greater depth. It provides the nexus for both inter- and intra-disciplinary debate.

The authors describe Jung as an intuitive thinker who relied firmly on the expression of many of his ideas as images, thus creating the ongoing phenomenon of his word usage and ideas as constantly changing. Thus the early momentum for writing the dictionary stemmed from, "a shared empathy between those struggling to understand". I am grateful for this struggle reaching the readers in such a useful form.

THE BRITISH JOURNAL OF PSYCHIATRY

October 1987 Vol 151

Published by
The Royal College of Psychiatrist

ISSN 0007–1250

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary.*

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al*, *British Medical Journal,* 7 May 1983, **286,** 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins,** and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that . . . '

DURKHEIM, E. (1897) Le Suicide. Paris. Translated (1952) as Suicide: A Study in Sociology, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. British Journal of Psychiatry, **124,** 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970) Education, Health and Behaviour. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In Pathology and Treatment of Sexual Deviation (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal,* should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

SYMPOSIUM ON ADDICTION

Over recent years the treatment of addiction has assumed increasing importance and this Symposium will focus on various aspects of addiction and how they relate to psychiatric practice today.

Speakers will include:

The Problem in Perspective
Professor A. Clare

Addiction—A World View
Dr. H. Ghodse

Addiction within the Profession
Dr. B. Wells

Addiction to Nicotine
Dr. M. Russell

Benzodiazepines and a Biological Model of Addiction
Professor M. Lader

The Addict 10 Years Later
Dr. G. Stimson

Treatment and Recovery from Addiction
Dr. J. Strang

This one-day Symposium will be held on:
Friday 20 November 1987
at
The Royal Society
6 Carlton House Terrace
London, SW1Y 5AG

The cost of registration will be £25 (£12.50 for junior medical staff.)
For further details of the Symposium and for registration forms, please contact:

UNIVERSITY OF OTAGO
and
OTAGO HOSPITAL BOARD
Dunedin, New Zealand
SENIOR LECTURER IN PSYCHOGERIATRICS

Applications are invited for the post of Senior Lecturer in Old Age Psychiatry within the Department of Psychological Medicine of the Faculty of Medicine, Dunedin. The appointee would be a member of an integrated care delivery system for the elderly based on a recently modernised hospital containing the Professorial Unit of Geriatrics in addition to the specialised psychogeriatric facilities. This hospital is a centre for innovation, both in care and research.

This is a joint University–Hospital Board post with University conditions of appointment, including a limited right of private practice and carrying consultant status. Applicants should be suitably qualified psychiatrists with clinical experience and an interest in research and teaching. The appointee would be involved in a full range of undergraduate and postgraduate teaching and would be encouraged to pursue their own area of research interest.

Salary Senior Lecturer NZ$57,800–$73,000 per annum. An allowance for clinical responsibility may be payable in the light of status and duties performed.

Intending applicants are invited to write for further information from the Secretary General, Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF, or from the Registrar of the University, P.O. Box 56, Dunedin, New Zealand.

Applications close on *16 October 1987.*

PSYCHIATRIST

The Public General Hospital, Chatham, Ontario is a 304 bed general hospital with a 30 bed inpatient psychiatric unit.

There are presently two psychiatrists who seek two others to share the workload. Sessional fees are available for services provided through a very active and progressive outpatient clinic operated by the Hospital. The outpatient service employs 19 professional and support staff in the various programs.

The Hospital serves a population of 100,000 and is located approximately 70 miles from London, Ontario and 50 miles from Windsor, Ontario and Detroit, Michigan.

Training and experience to meet Ontario certification eligibility requirements are necessary. An interest in child and adolescent psychiatry would be welcome.

Please forward curriculum vitae or request for additional information to:

Chief of Psychiatry
Public General Hospital
106 Emma Street
Chatham, Ontario N7L 1A8
CANADA

Telephone (519) 352-6400, ext. 227

ST. PATRICK'S HOSPITAL
P.O. BOX 136
JAMES'S STREET, DUBLIN 8, IRELAND

CONSULTANT PSYCHIATRIST
(With Special Interest in Alcoholism)

The Governors of St. Patrick's Hospital invite applications for the above position. The hospital which caters mainly for short-stay psychiatric patients is a university teaching hospital and has a long established and comprehensive treatment programme for alcoholism.

Further information may be obtained from:

The Secretary/Manager,
St. Patrick's Hospital,
at the above address,

to whom formal applications should be submitted before 30th October, 1987.

Treatment of Autistic Children

by P. HOWLIN and M. RUTTER, both of the Institute of Psychiatry, London, UK
(with M. BERGER, R. HEMSLEY, L. HERSOV and W. YULE)

The treatment programmes discussed in this book are individually designed for each child with the help of the parents who act as the principal therapists and are derived from both developmental and behavioural psychology. In addition to evaluating the progress made by individual children, the authors compare the outcome against matched group controls to assess the most overall effective treatment.

0471102628 304pp October 1987 £29.50/$58.45

Self, Symptoms and Psychotherapy

Edited by N. CHESHIRE, Ysbyty Gwynedd, Bangor, Wales and H. THOMAE, University of Ulm, Germany

This volume examines the way in which disturbances in Self functions may underlie the familiar neurotic disorders of depression, anxiety, obsessions, phobias and psychosomatic malfunctions (as well as certain personality traits and defects), the symptoms of which are presented every day to psychiatrists, clinical psychologists, psychoanalysts *et al*, and at which various types of psychotherapy are directed.

0471905488 312pp September 1987 £34.50/$68.35

The Origins of Modern Psychiatry

Edited by C. THOMPSON, Charing Cross and Westminster Medical School, London, UK

This collection of thirteen works covers some of the outstanding contributions made in the period 1856 to 1938, a time of extraordinary change in which the foundations of present-day practice were laid down. Each original paper is accompanied by a commentary written by a modern expert in the field, which sets the work in historical context and demonstrates its relevance to modern practice.

0471915815 approx 262pp October 1987
approx £25.00/$49.50

Biological Perspectives of Schizophrenia

Edited by H. HELMCHEN, der Freien Universitat, Berlin, Germany, and F.A. HENN, Health Sciences Center, New York, USA

The purpose of this book is to examine the biological processes involved in the etiology and pathogenesis of schizophrenia, to define gaps in our knowledge, and to provide directions for future work. Genetic and nongenetic factors, structural and functional deviations, and neurotransmitters are comprehensively reviewed.

0471916838 approx 360pp October 1987
approx £42.00/$84.15

Epilepsy

Progress in Treatment

Edited by M. DAM, M. SILLANPAA, S.I. JOHANNESSEN, B. NILSSON

This book serves to bridge the gap between intensive neurophysiological, pharmacological and psychiatric studies in the field of epilepsy and the everyday practical care problems in its diagnosis, the many aspects of drug treatment, the many new antiepileptic drugs under development and, the management of comprehensive care programmes. The emphasis is on application to patient management and this book represents the first European contributed volume on the state-of-the-art of practical care of the patient with epilepsy.

0471916803 approx 308pp August 1987
approx £37.00/$73.30

Biological Psychiatry

by M.R. TRIMBLE, Consultant Physician to the Department of Psychological Medicine, National Hospital

This book explores the biological foundations of psychopathology and describes the historical development of a medical approach to psychiatric illness, showing how therapeutic advances have conquered diseases previously considered incurable. Recent progress in biological psychiatry especially relating to the major psychoses, epilepsy and dementia, is reviewed.

0471916226 approx 535pp January 1988
approx £35.00/$69.30

Human Psychopharmacology

Volume 1: Measures and Methods

Edited by I. HINDMARCH and P.D. STONIER, Human Psychopharmacology Research Unit, University of Leeds, UK

Internationally respected researchers discuss the use and development of test systems, the definition of research domains, the pragmatics of human experimentation, the application of experimental findings to therapeutics, and the establishment of appropriate measures whereby the efficacy and safety of modern psychopharmaceuticals can be assessed.

0471912387 254pp April 1987 £24.50/$45.85

INSTITUTE OF PSYCHIATRY

Training Course in Cognitive Behavioural Therapy

There will be a training course in Cognitive Behavioural Therapy at the Institute of Psychiatry between January and June 1988. The course starts with a two day workshop on 22–23 January and thereafter every Friday morning between 9.30 am and 1.00 pm, until 10 June.

Students will be expected to treat patients under supervision, and will attend a series of academic seminars. Psychiatrists and post-qualification psychologists are likely to be particularly interested, though applicants from other professional disciplines will be considered. Numbers will be limited.

For further details apply to the Registry, Institute of Psychiatry, De Crespigny Park, Denmark Hill, London SE5 8AF. Closing date for applications: 30 October 1987.

Consultant Psychiatrist - Swaziland

The Overseas Development Administration provides a wide variety of assistance to countries in the developing world. This aid can be in the form of organising development projects, supplying technical help and consultancy or assisting with the recruitment of specialist staff.

Swaziland's Ministry of Health currently requires a Consultant Psychiatrist to work in Matsapa Mental Hospital. The main responsibilities of the post are for the training of Psychiatric Nurses and Junior Medical Officers.

Applicants must be British citizens aged less than 60 who are members of the Royal College of Psychiatrists. Five years or more relevant post graduate experience is essential.

The appointment is on contract to the Government of Swaziland for a period of 30 months. Local salary is in the range Lilangeni 18,420 to 20,766 pa, plus a tax free supplement, payable by ODA, in the range £17,832 to £19,656 pa. A terminal gratuity of 25% of local salary is also payable. Other benefits normally include free passages, children's education allowances and subsidised accommodation. Exchange rate as at August 1987 - £1 stg=3.30 Lilangeni.

For an application form, please write, quoting ref. AH364/JM/BJP, **stating post concerned,** to: Appointments Officer, Overseas Development Administration, Room 351, Abercrombie House,
Eaglesham Road,
EAST KILBRIDE,
Glasgow G75 8EA.
Or telephone 03552 41199
extension 3527.

NEW PUBLICATIONS

FREEMAN, T. THE PSYCHOANALYST IN PSYCHIATRY (Cloth) £20.00
(Paper) £ 9.95

Great changes in the patient population of psychiatric hospitals and in methods of management and treatment have taken place in the last 30 years. Although the functional psychoses and organic mental states are still seen in large numbers, reactive depression, personality disorder, alcoholism and neuroses form an increasingly significant proportion of hospital admissions. Thus the psychoanalyst who chooses to work within psychiatry makes a contribution at two levels: therapeutically, in elucidating the innermost thought and feelings of the mentally ill; and theoretically, in pointing to the common elements in the mental life of the healthy, the psychotic, the neurotically afflicted, and the brain-damaged.

SANDLER, J. FROM SAFETY TO SUPEREGO (Paper) £14.95

Joseph Sandler is known to students of psychoanalysis the world over as one of the chief figures of psychoanalytic theory for the past 25 years. His writings have been immensely influential in setting the directions of theoretical reflection and articulating the dominant themes of the still emerging 'talking cure'. This comprehensive volume brings together for the first time the many divergent elements of Sandler's rich reconceptualization of psychoanalytic thought.

ANNE'S STORY

Anne had thought she was going to die Her heart was pounding, she felt she could not breathe. Her one thought had been to get out of the store as quickly as possible, abandoning her half filled trolley she had pushed past the waiting queue.

That had been a year ago and she still could not go into a supermarket — even the local shop was a source of terror.

Her husband had taken over most of the shopping — but now her panics were occurring at home and he was missing work because she could not tolerate being alone

There are many women with this type of problem who can be helped to regain control of their lives, by appropriate psychological treatment.

St Andrew's Hospital offers an intensive four to six week treatment programme for this type of problem.

For further details write or telephone Kathy Perkins Admissions Officer

The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine[1] trifluoperazine[2] and haloperidol[3] but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia[4]

sulpiride

Dolmatil™

IN SCHIZOPHRENIA

MENTAL HEALTH CARE

SQUIBB®

Prescribing Information Dolmatil Tablets: Plain white round tablets with a transverse breaking line on one side and the mark D200 on the other. Each tablet contains 200mg sulpiride **Indications:** Acute and chronic schizophrenia **Dosage:** A starting dose of 400mg to 800mg daily, given as one or two tablets twice daily (morning and early evening) is recommended **Predominantly positive symptoms:** Starting dose of at least 400mg twice daily, increasing if necessary up to 1200mg twice da **Predominantly negative symptoms:** Starting dose of 400mg twice daily reducing as required towards 200mg twice daily **Mixed positive and negative symptom** 400mg-600mg twice daily The same dose ranges may be required in the elderly, but should be reduced if there is evidence of renal impairment Clinical experience in children under 14 years of age is insufficient to permit specific recommendations **Contraindications:** Phaeochromocytoma **Warnings** Extrapyramidal reactions principally akathisia have been reported in a small number of cases If warranted, reduction in dosage or anti-Parkinsonian medication may be necessary After over a decade of widespread use in many countries, tardive dyskinesia has occurred rarely, insomnia has been reported, increased motor agitation has been reported at high dosage in a small number of patients: in aggressive, agitated or excited phases of the disease process, 'Dolmatil' may aggravate symptoms. Care should be exercised where hypomania is present Galactorrhoea, amenorrhoea and gynaecomastia may occur in association with hyperprolactinaemia **Precautions:** Epilepsy – anti-convulsant therapy should be continued unchanged Impaired renal function, as sulpiride is eliminated via the kidney Pregnancy – the general principle of avoiding drug treatment during pregnancy, particularly during the first sixteen weeks, should be followed **Product Licence Number:** PL 5299/0006 **Legal category:** POM. **Basic NHS cost:** 63p per day at dose of 600mg daily **Name and address of Distributor:** E R Squibb & Sons Ltd, Squibb House, 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. •Trade Marks of E R Squibb & Sons Ltd (Distributor) DOLMATIL – Trade Mark of SESIF Authorised User Delagrange Ltd **References** 1 Harnryd C et al Acta Psychiatr Scand 1984,69. Review Article

Mental Health in Africa:
I. The Extent of Mental Health Problems in Africa Today
An Update of Epidemiological Knowledge

G. ALLEN GERMAN

This paper is concerned with steadily developing knowledge of the epidemiology of some psychiatric disorders in sub-Saharan Africa. The diversity of 'Black Africa' is noted, and preconceptions about African psychiatry briefly discussed. Problems of sociological versus clinical philosophies are also mentioned. Early estimates of prevalence of psychiatric disorder in black Africa were universally low, being based on hospital data. More recent studies, sampling diverse populations, suggest a burden of psychiatric morbidity in black Africa which is not dissimilar to that found in more developed countries, and some studies suggest that rates in Africa may even be higher than in developed countries.

This two-part review, is concerned with mental health problems among black African people living in sub-Saharan Africa. In particular, research data obtained in anglophone countries will be emphasised, while bearing in mind that such data are not necessarily applicable to the entire continent. The intention is to update an earlier review (German, 1972).

The area under consideration is frequently regarded as homogeneous from traditional European viewpoints. In reality 'Black Africa' is exceedingly diverse: physically, culturally and socially it is very different from Europe and North America. From the point of view of the psychiatrist this is of great importance, since it permits mental disorder to be studied in a setting which maximises the difference between important background variables which have been thought to have aetiological significance in the production of disturbed human behaviour. If, despite differences in geography, climate, ethnicity, culture, and socio-economic structure, mental disorders are more or less similar to those found in other parts of the world and among other races of mankind, this argues a fundamental consistency in the expression of mental abnormality intrinsic to man himself. If, on the other hand, disturbances of behaviour show major differences with varying environments and cultures, then these disorders are more complex psychosocial reactions to varying life circumstances, highly diverse in their manifestations and courses, and unique to the individual and his personal life experience.

Before the 1960s, the decade of African independence, it was customary to regard mental ill health as being rare in Africa. Colonial psychiatrists such as Tooth (in Ghana) and Carothers (in Kenya) found evidence from their surveys of hospital populations to support the view that mental ill health was particularly uncommon among Africans, compared with Europeans. This idea sprang in part from the idyllic philosophies of Rousseau, and in part from the usually unstated belief that mental ill health was part of the price that Judaeo-Christian cultures had to pay for civilisation, for being responsible, and for opposing the Devil and all his works. In that same pre-independence era, generalisations about Africans included the views that their brains were inferior, that they functioned in a childish manner, and that they lacked a sense of responsibility. Their emotional distress was the short-lived and charming emotionality of the child, but not the bravely-borne pain of affective disorder. Responsibility was defined in terms of European priorities, while the responsible pursuit of African values was usually regarded as evidence of backwardness. Thus a series of cultural stereotypes was imposed on the African, and confirmation for these stereotypes came from epidemiological inquiries limited to patients in custodial mental hospitals – a highly selected and unusual population.

This sort of polemics tend to simplify the situation and ignore realities (such as the fact that a large number of Europeans are childish in their behaviour, lack a sense of responsibility, and spend nearly as much money on traditional European healers as they do on organised health services), and well illustrate the problems in determining the extent and nature of mental health and illness in Africa.

Great shortages of skilled manpower, particularly with adequate research training, persist in Africa. This is not entirely due to a lack of scientists who wish to work in Africa. Researchers with extensive experience of African clinical psychiatry, be they African or expatriate Europeans, are few in number, and since in most cases they have to cope with heavy service demands their experience of African clinical settings cannot be taken advantage of in research work. The visiting researcher is handicapped by lack of knowledge of language, custom, and culture, and by lack of day-to-day familiarity with the common modes of presentation of psychiatric disorder. This is a serious handicap which is not always apparent to the trained clinician undertaking research in his own culture.

The data base with regard to demographic structures and patterns is sadly inadequate. Also lacking are adequate data-processing facilities and laboratory facilities for biological investigation. These problems are further compounded by communication and transportation problems: by the sheer size of the areas to be studied, by inadequate libraries and literature resources, and by linguistic diversity which is a problem for even the well-trained African professional.

In addition to these practical problems are those which result from philosophical issues. European researchers may produce immaculate work, but be vulnerable to the charge of ethnocentricity blinding them to more subtle aspects of African psychopathology and culture. This has become less of a problem, since the majority of psychiatrists now working in anglophone Africa are native Africans with extensive experience in their own societies. A substantial amount of research now emanating from black Africa has been undertaken by black African clinicians; this is a development of considerable significance.

Ethnocentricity is not the only factor, however, which can distort conclusions. It is perhaps significant that non-psychiatric researchers are those most likely to conclude that African mental health and mental disorder is culture-bound and not capable of being comprehended within Western psychiatric categories. To be fair, it is also of significance that most of those who insist that mental disorder in Africa is comparable with that found in Europe and North America, and is susceptible to similar classification, are clinical psychiatrists (albeit now mostly African ones). Among psychiatrists who repudiate nosological and classificatory systems of a Kraepelinian or DSM-III type are to be found large numbers whose interests are primarily in psychoanalysis, social psychiatry, or psychiatric anthropology. The viewpoint clearly influences the conclusions reached.

The extent of mental disorder

Early studies of the extent of mental disorder in Africa relied almost exclusively on hospital statistics. Most colonial African countries had one central mental hospital to which patients were brought, usually because they had become violent and disruptive within their communities. This may be why hospital statistics repeatedly indicate an excess of male admissions over female (usually in a ratio of two to one). These hospital studies led to the conclusion that in most parts of British Africa the point prevalence of psychiatric disorder varied between 0.1 per 1000 at risk (Carothers, 1953) to 0.96 per 1000 (Tooth, 1950). Carothers also obtained information from district commissioners and chiefs, and suggested a figure of 0.37 per 1000 at risk as representing the prevalence of psychiatric morbidity in Kenya.

All these statistics, if taken at face value, would suggest an extremely low prevalence for mental disorder in Africa. They also indicate a relatively low admission rate to psychiatric hospitals, compared with more developed parts of the world. The great range in the figures (0.1–0.96) indicates their probable unreliability.

In view of the tendency to select violent patients for hospital admission, the authors of these reports were not in a position to describe adequately the occurrence and nature of psychoneurotic disorders, or of the 'quieter' psychoses such as psychotic states of depression. The absence of such forms of pathology among their case material led to the supposition that these disorders were exceedingly rare in Africa.

In a previous review (German, 1972) some note was made of the difficulties which still plague studies of prevalence in Africa. Problems relating to the definition of psychiatric disorders – particularly conditions such as the neuroses and personality disorders, where it is important to establish cut-off points to distinguish what will be considered a case and what will be excluded – have only recently been tackled in the African context. Consequently, earlier studies of prevalence, based on field research, have either sought to avoid diagnostic definitions or have suffered from uncertainties as to what was being counted.

Epidemiological questions

In the face of these problems several strategies have been employed, each seeking to answer different sorts of question about prevalence:

(a) What is the prevalence of psychiatric morbidity among accessible and easily studied populations?

(b) What proportion of general hospital clinic attenders are primarily psychiatrically disturbed?

(c) How many Africans from a given community consult someone because of psychiatric disorder in the course of a year?

(d) If one samples a total population, what is the point prevalence of significant psychiatric morbidity in that population in the African setting?

Prevalence in accessible populations

One of the easiest groups to study with epidemiological techniques is one of university students. African universities tend to be self-contained, and provide comprehensive internal health services. All students are registered with and examined by the health service on admission, and continue to rely on its services throughout their student career.

German & Arya (1969) published results of a study of psychiatric morbidity among the students of Makerere University College. They used the same techniques as Kidd & Caldbeck-Meenan (1966) used for a similar study at the Universities of Edinburgh and Belfast. The overall annual prevalence for significant psychiatric morbidity among the student body at Makerere was 10.8%, compared with 11.6% in Edinburgh and 10.2% in Belfast. These figures were broken down into broad categories of psychiatric diagnosis; 6.7% of the Makerere patients were psychotic, 85.9% were psychoneurotic, and 7.4% were thought to show significant disorders of personality. Comparable figures for Edinburgh were 4.6%, 90.2%, and 5.2% respectively; for Belfast they were 2.0%, 91.0%, and 7.0%.

Other studies of African student populations have since been carried out. Jegede (1980) surveyed 145 female and 725 male first-year students at the University of Ibadan in Nigeria. The Health Opinion Survey, the Eysenck Personality Questionnaire and the 65-item General Health Questionnaire were used, as well as self-ratings of mental health. Overall, 6.3% of the group rated their mental health currently and during the preceding 4 weeks as being poor or only fair. The methodology of this study was different from that of German & Arya, and the prevalence rates obtained cannot be directly compared. However, Jegede pointed out that his rates were remarkably close to the prevalence rates of 7–16% reported by Segal (1966) in a review of five such university studies carried out since 1960.

While these college studies cannot be directly compared, they suggest a weight of psychiatric morbidity in African students which is comparable with that in the developed world; this seems to hold true even for the distribution of diagnoses across the broad categories of psychoses, psychoneuroses and personality disorders. African students might be regarded as closely comparable to students anywhere else, but it should also be remembered that these students, although an élite, have been brought up within their distinctive cultures, with personality traits and attitudes, belief structures and behaviours, and concepts of illness which closely approximate those to be found within the greater culture around them. In general, there is little evidence to suggest that being intelligent, being African, or having gone to university particularly protects young Africans from mental ill health.

Research interest has also been directed at the psychiatric status of pregnant and puerperal women in Africa. In a detailed and extensive study, Cox (1979) compared 263 pregnant Ugandan women with 89 non-pregnant women, using a semi-structured psychiatric questionnaire. He reported that 16.7% of the pregnant women had definite psychiatric disorders, and that a further 14.1% showed possible psychiatric morbidity; the comparable figures for the non-pregnant women were 7.9% and 4.5%. Of the pregnant women, 8% suffered from a depressive neurosis, 2% from a depressive psychosis, 3.4% from an anxiety neurosis, and 1.9% from a phobic neurosis. Cox noted that the "belief that Africans have a trouble-free natural pregnancy is not substantiated". His results confirm a report by Assael *et al* (1972) that 24% of pregnant women in the same population showed evidence of conspicuous psychiatric morbidity, the bulk of which was of a depressive sort. It is of interest that both these Ugandan studies report prevalence rates in excess of rates reported from Europe: 17.1% in Sweden (Nilsson & Almgren, 1970) and 16% in Britain (Kumar & Robson, 1978). Cox noted an association between psychiatric morbidity during pregnancy and marital separation.

Another study of puerperal psychiatric disturbances has been reported from Tanzania (Harris, 1981). Harris found that 38% of puerperal Tanzanian women showed clear evidence of 'maternity blues' and commented that the prevalence of such disturbances in these East African mothers is similar to that in other cultures. He concluded that 'maternity blues' are supra-cultural in their manifestations.

Psychiatric disorder among general hospital out-patients

A considerable number of African studies have addressed this question. It is important that hospital administrators and health planners should be aware of the frequency with which people with primary psychiatric disorder are being dealt with in general clinics by health personnel who may have little familiarity with psychiatric morbidity.

One of the older, but most detailed, studies of this sort was carried out in Ethiopia by Giel & Van Luijk (1969). They reported that 18.5% of general out-patients attending a teaching hospital in Addis Ababa were primarily suffering from psychiatric conditions, compared with only 9.5% diagnosed as suffering from infectious diseases. In a more rural population served by a provincial general hospital only 7% of general out-patients were found to be psychiatrically ill, while 28.7% demonstrated evidence of infectious disease. Finally, at a rural health centre serving a totally unselected and largely self-referred population (akin to a general practice in the western world) 19.5% of out-patients were deemed to have psychiatric disorders, and 17.1% to have infectious diseases. This study is of particular interest in that it provides statistical comparisons with infectious diseases, which occupy the forefront of medical attention in Africa and other developing regions.

A Nigerian general practitioner with a special interest in psychiatry reported that 1460 new patients attended his general clinic over a period of three months (Mbanefo, 1971). The 1732 diagnoses made included 265 cases of malaria, 264 of psychiatric disorder, 181 of respiratory infections, 262 of other infectious diseases, and 55 of gynaecological problems. Overall, 15% of his patients, drawn from mixed urban and rural populations, were diagnosed as having a psychiatric disorder. A more recent study of this sort was reported from rural Kenya by Ndetei & Muhangi (1979). Patients seen at a walk-in/walk-out clinic over a period of 30 days were surveyed. Of 140 patients, 20% were found to be psychiatrically disordered and 59.3% physically ill; the diagnosis of the remaining 20.7% was uncertain. The majority of the psychiatric cases showed anxiety and depressive symptoms.

Thus it would appear that in relatively unselected attenders at general out-patient clinics in Africa approximately 20% are primarily psychiatrically disordered. Most of these reports stress the frequency with which psychological distress is presented as somatic disturbance. Such modes of presentation are particularly confusing to the general health worker without experience of psychiatry.

Consultation rates in a given community

Studies designed to answer this sort of question are difficult to undertake in Africa: they require a field approach to either a total population or a representative sample, or a thorough search of all possible consultation agencies in an attempt to locate attendees.

Two studies have provided information in this area. Giel & Van Luijk (1969), in addition to the hospital and health centre investigations discussed above, surveyed a defined catchment area in an attempt to discover how many people in that area consulted someone for psychiatric illness in the course of one year. The authors used the rural area in which the rural health centre was established, and in addition to consultations with official health agencies sought data on persons consulting local healers and witch-doctors. They believed that few consultations were missed using this technique. They found an annual consulting rate for psychiatric disorder of 148 per 1000 of the population at risk, and compared this with the rate of 139.4 per 1000 for England reported by Shepherd *et al* (1966).

In contrast to this, Binitie (1981) found a rate of 35.7 per 1000 at risk in a rural area of Bendel State in Nigeria. The population studied comprised 2325 workers on an oil palm plantation, relatively isolated from surrounding populations and provided with an internal health service. Binitie does not appear to have taken account of other consultation agencies, although he points out that the families and dependents of the workers were in the habit of consulting away from the unit health centre. Nor is mention made of whether or not these subjects consulted with traditional and native healers, and in view of the well-established organisation of such healers in Nigeria it seems likely that substantial numbers of the catchment population might have been missed as a result.

Point prevalence in a total population

Two epidemiological studies are worthy of mention in this context. They were conducted over a decade apart and utilised different methodologies. The first was carried out in Western Nigeria, in urban and rural populations around the city of Abeokuta (Leighton *et al*, 1963). The methodology was designed to produce data comparable to those obtained in similar researches in Canada. African subjects, male and female, living in the urban area and in rural villages were assessed in terms of the presence of specified psychiatric symptoms rather than in terms of diagnostic groups or syndromes. It was found that 21% of the respondents in the villages and 31% of those in the city showed significant symptoms of psychiatric morbidity at the time of the survey. Probable psychiatric symptoms were present in a further 19% of villagers and 14% of city dwellers. The authors provided a wealth of data, but perhaps their most significant comment was that in comparison with Canadian samples "the similarity of the two samples is much more impressive than the differences. In view of the contrast between the cultures and life situations, this is truly remarkable. The similarity applies both to pattern quality (anxiety, depression, etc.) and to prevalence in most of the categories tabulated".

The second study approximates more closely to the ideal epidemiological study than any other carried out in black Africa to date (Orley & Wing, 1979). These workers sought to establish data on psychiatric morbidity for a total population sample. Orley conducted the fieldwork in rural Uganda, using techniques developed by Wing for the assessment of psychiatric symptoms and their categorisation into psychiatric syndrome groups. Data obtained from south-east London in a similar manner were available for comparison. Total populations in two small Ugandan villages were interviewed using the Present State Examination (PSE) and standard methods of case identification. The data obtained were then analysed using an index of definition to establish cut-off points and the CATEGO program for syndrome identification. Orley is an experienced psychiatrist, and is also qualified in anthropology. At the time of the survey he had spent several years working in rural Uganda, conducting anthropological researches through participant observation. He had learnt the local language, Luganda, to a high level of fluency. He also used the PSE as translated by himself into Luganda, following extensive work with local Luganda speakers and scholars to establish the validity of the translation. The methodology is meticulously described, and potentially repeatable given a similar investment of labour. A number of aspects of this study make it a highly significant piece of work, the results of which require careful attention. They include the careful methodology, and the facts that a total population was sampled, that standardised and reasonably objective methods were used to obtain and analyse data, and that the population in question was rural and remote from Western influence, subsisting in a traditional manner.

Orley & Wing reported the prevalence of psychiatric morbidity at varying levels of certainty or definition. Eight levels of confidence are used, level 5 being the threshold and levels 6–8 indicating increasing degrees of confidence that the symptoms present could be classified into one of the categories of functional psychoses or neuroses used in the International Classification of Diseases (World Health Organization, 1978). In brief, 4.9% of the total population showed definite psychiatric syndromes, with an additional 20.4% of the population showing evidence of psychiatric distress at threshold level. There was no difference between the proportions of each sex showing definite psychiatric syndromes, and little difference at the threshold level. Combining all cases at threshold level and above, 27% of the women and 24% of the men showed evidence of psychiatric disorder. In comparison, the authors reported that in a suburb of South-East London 11% of women showed evidence of psychiatric disorder at above-threshold level – i.e. the point prevalence of psychiatric morbidity in rural Urganda is at least twice that found in South-East London.

With regard to syndrome categories, Orley & Wing reported that 2% of the men and 2.2% of the women in their population showed evidence of hypomania (compared with 0.4% among women in South-East London); evidence of depressive disorders was found in 14.3% of the Ugandan males, 22.6% of the Ugandan females, and 9.3% of the South-East London females. Anxiety states were detected in 3.1% of the Ugandan males, 4.3% of the Ugandan females and 1.3% of the South-East London females. Particularly striking is the high frequency of depressive disorder; this will be discussed in Part II of this paper.

As this study used the most sophisticated and exacting methodology employed to date in tackling the problem of the prevalence of psychiatric morbidity in Africa, its results must be refuted or replicated as a matter of some considerable urgency. Until that is done it must be taken as the best evidence available relating to the extent of mental illness in African populations.

This brief review of studies of prevalence in Africa has focused on the more significant studies. There is a wealth of data available based on clinic and hospital populations, which has not been commented on. However, the general trend is clear: the extent of mental illness in black Africa is at least as substantial as in other parts of the world where data have been obtained, and there is some disturbing evidence which suggests that morbidity rates may be even greater. Furthermore, the frequency of psychotic and psychoneurotic illnesses also appears to be approximately the same as elsewhere. Finally, despite previous assertions to the contrary, among these common psychoneurotic presentations the familiar symptoms of depression and anxiety seem to be as ubiquitous as everywhere else.

British Journal of Psychiatry (1987), **151**, 440–446

Mental Health in Africa:
II. The Nature of Mental Disorder in Africa Today
Some Clinical Observations

G. ALLEN GERMAN

Aspects of clinical psychiatric syndromes described in Africa which are discussed include the issue of schizophrenic disorders having a better prognosis in developing countries; controversy over this is by no means at an end. There is an increasing realisation as to the frequency of affective disorders in Africa; while somatisation is common, cherished beliefs, such as the absence of guilt, have not been confirmed by more recent research. Nor is suicide as infrequent as has been suggested. The relationship of background physiological abnormalities of cerebral functioning may be relevant to some of the clinical issues that are currently under discussion in African psychiatry.

An important question at the operational level is whether or not defined criteria for a given mental disorder can be shown to apply in Africa with reliability comparable to that obtained in more developed parts of the world. It is only in the past 20 years that attempts have been made to produce detailed operational definitions of psychiatric symptoms and to train psychiatrists and other research workers in the reliable use of such definitions. The Present State Examination (PSE) (Wing & Sturt, 1978) is an example of development in this area. It was one of the first such instruments to be developed and applied widely in different cultures; its use by Orley in Uganda was described in Part I of this review. Other standardised systems of psychiatric symptom elicitation have been developed, together with standardised definitions of syndrome complexes built on these symptoms. The availability of such tools enables psychiatrists in different settings, provided they have had comparable training, to study the distribution of symptoms and syndromes in various cultures and to draw conclusions as to the nature of such phenomena in various parts of the world.

Schizophrenia

Recognising the potential of these developments, the World Health Organization has pioneered research approaches to various psychiatric disorders, with the intention of obtaining information on the distribution of psychiatric symptoms and syndromes in those parts of the world where culture and ethnicity differ widely from the Western society in which current concepts of psychiatric disorder were developed. Foremost among these studies is the International Pilot Study of Schizophrenia (IPSS), a multi-centre examination of the symptom profiles of psychotic patients in eight different locations throughout the world. One of these is at Ibadan (in Oyo State, Nigeria); the others are in the UK, the USA, the USSR, India, Denmark, Czechoslovakia, and Colombia. The IPSS, in its initial phase, was not concerned with establishing the prevalence of schizophrenia but with determining whether or not (a) psychiatrists in different parts of the world could use tools such as the PSE reliably, and (b) schizophrenia, as defined by standardised criteria, could be identified in disparate cultures. The answer to both these questions has been found, after a decade of intensive work, to be in the affirmative (Luria & McHugh, 1974; WHO, 1973; WHO, 1975; Wing & Sturt, 1978). Schizophrenia occurs in black Africans with the same presenting symptoms and the same patterns of symptoms as were originally described in Europe during the first decade of this century, and thus many of the controversies which raged in the African psychiatric literature some fifteen years ago have now been settled.

A previous review (German, 1972) discussed problems relating to the distinction between 'process schizophrenia' and schizophrenia-like syndromes occurring in such settings as organic disease, epilepsy, or psychogenic stress. Many psychiatrists in Africa made no distinction between these two groups; others insisted that a diagnosis of schizophrenia should only be made in the absence of organic disease, or where affective, confusional, and comprehensible psychological symptoms were not dominant in the clinical picture. As a result of these differences, there was considerable controvery as to the profile of schizophrenic symptoms in Africa and dispute as to prognosis. Those with the broader concept of the disorder reported greater heterogeneity of outcome, while those with more restricted notions argued forcefully that schizophrenia in Africans was identical to that seen in Europeans (Boroffka, 1964; Fortes & Mayer, 1969). Such differing concepts of schizophrenia are bound to lead to controversy. However, with the selection of accepted operational definitions for the symptoms of the disorder, and diagnostic criteria in terms of the profile of symptoms, it becomes possible to seek answers to fundamental questions about schizophrenia.

A different view of schizophrenia could lead to a different and better prognosis for patients in developing Africa than in the developed world: if workers in Africa were using a concept of schizophrenia which included many short-lived transient reactions to organic, affective, and psychogenic precipitants, then schizophrenia in Africa would have a better prognosis than elsewhere. Undoubtedly, some of the impression of good outcome is attributable to such factors. However, with the development of the IPSS methodology it has now become possible to follow up defined cohorts of schizophrenia in different parts of the world. The IPSS goes to some lengths to exclude organic, affective, and psychogenic psychotic states and, given that the described method of assessment has been properly followed in each centre, there is evidence to suggest that schizophrenia, even thus defined, has a better prognosis in certain developing societies than in more developed ones. The matter is still not entirely settled, since there remain some inadequacies yet to be dealt with in this major study (Day, 1980).

Murphy (1976) studied local and traditional definitions of insanity in Eskimo and Yoruba (Nigerian) cultures. This study is of particular interest because the author, an anthropologist, confesses to conclusions contrary to her expectations. She produced evidence that insanity, comparable with European concepts of psychosis, is recognised and named on the basis of the same patterns of disorder in culturally disparate groups. In addition, she advances evidence for the universality of the psychoneurotic experience, and also for similar prevalence rates of all these categories of disorder throughout the world. She stated, "Rather than being simply violations of the social norms of particular groups, as labelling theory suggests, symptoms of mental illness are manifestations of a type of affliction shared by virtually all mankind." Her explorations of this matter are particularly concerned with schizophrenia, and her eloquent descriptions of Eskimo and Yoruba concepts of this disorder are strikingly similar to those of Kraepelin.

Depression

Another area of considerable discussion concerns the nature of depression and other affective psychoses in the African setting. During the colonial period it was generally stated that depressive illness was rare in Africans (Prince, 1968). Prince pointed out that up to 1957 13 out of 14 authors reported that true psychotic depressions were rare, and that if they did occur they were short-lived and of little severity (the exception was Field (1960)); in the period 1957–1968, 21 papers were published which expressed the contrary view. He suggested that while there may have been a real increase in the prevalence of depressive illnesses, it seemed more likely that when studies were based mainly on hospital populations, cases of depression were rarely detected, since they were rarely admitted to institutions. He also suggested that in the pre-independence era depression was implicitly regarded as the 'property' of people with certain attitudes to life: responsible Judaeo-Christian attitudes, saturated with the work ethos. Another possibility is that more modern views of depression, which include the concept of depressive illness without marked emotional shift (masked depression) have enabled recent researchers to detect a far greater number of depressive syndromes in African populations. Finally, depression achieves its greatest frequency in persons over the age of forty; since in most African populations statistics indicated that until recently few Africans lived beyond this age, it may be that with increasing life expectancy more cases of depression are becoming apparent. Clearly, age-specific rates must be calculated for any valid study of this problem.

Current workers are unanimous in agreeing that depressive illness, psychotic or otherwise, is common in Africa. Dispute persists, however, about the nature of symptoms. Asuni (1961) concluded that feelings of guilt were rare and that paranoid projection was a more common feature of depressive illness in Africa. Binitie (1975), in a sophisticated statistical study, concluded that, while depression seems remarkably similar in Nigeria and London, somatic symptoms are commoner in Africa, and guilt with suicidal ideas commoner in England. Most workers would have agreed with Binitie (including the present author, who has presented evidence (German, 1972) to support the view that ideas of guilt were relatively rare in African subjects), were it not for the more recent work of Orley & Wing (1979), who found no support for these earlier opinions.

In view of the methodological precision of the Orley & Wing study, and particularly in view of Orley's substantial familiarity with the language of his study population, their findings must be given due attention. They report a frequency of pathological guilt among the Ugandan subjects which is approximately four times greater than that found in London. This is entirely opposed to previous viewpoints, and may either represent a constellation of symptoms peculiar to a limited area, or demonstrate that the history of exploded myths in African medicine continues to be written. In view of the significance of this study, it can no longer be stated with certainty that feelings of guilt are only found in highly individuated people brought up in nuclear families which tend to emphasise personal responsibility.

The issue here may not be so much whether individual symptoms are present or absent, but the extent to which given population groups emphasise these symptoms in their concept of priorities – or in their concept of what is appropriate in a state of illness. It would appear that most African patients present somatic symptoms in depression frequently and with considerable force, in keeping with their view of the nature of states of disease and with their relative psychological unsophistication. It is not inconceivable that in all depressives there are equal feelings of somatic unease and of guilt; the extent to which either of these is presented may be merely a reflection of culturally determined assessments of priority or relevance.

Suicide

The prevalence of suicide in Africa is another area of dispute. Some studies have found suicide rates to be low; Asuni (1961) and Laubscher (1937) quoted annual rates of approximately one successful suicide per 100 000 persons in Nigeria and South Africa respectively. However, Fallers & Fallers (1960) found 8.5 suicides per 100 000 in the Busoga District of Uganda, while Rwegellera (1978), compiling rates from the city of Lusaka in Zambia, reported an overall annual suicide rate for Africans of 12.8 per 100 000. The comparable rate in Lusaka for Europeans was 20.9 per 100 000.

Rates therefore range from those which are exceedingly low by European standards to those which are comparable with figures reported from European countries such as Britain. The reasons for these differences are not clear. Certainly suicide is not an easy behaviour to diagnose accurately, particularly in countries where police and judicial services may be meagre. In addition, as Orley (1970) has pointed out, suicide in most African cultures is regarded as a terrible act, which attracts cultural sanctions (including secrecy) which may well distort reports of its occurrence. On the other hand, it could be argued that more recent studies such as that by Rwegellera have concerned themselves with urban populations in large cities which are undergoing rapid and traumatic social change, a situation ripe for the enhancement of suicide. The matter is not yet certain, but it appears that in traditional and stable African communities suicide rates are somewhat lower than in those other African communities, both rural and urban, which have been exposed to social changes during the past 20 years.

Transient psychoses

In the earlier discussion of schizophrenia, it was noted that short-lived transient psychotic reactions to various precipitants are particularly common in Africa. Most authors who have written about African psychiatry have commented on this, with occasional exceptions such as Rwegellera (1977). These states have been previously discussed in some detail by the present author (German, 1972; Assael & German, 1970). Various names are applied to the states, the commonest used in anglophone Africa probably being 'acute psychotic reaction'. They are variously described, and appear to form an amorphous category characterised by features such as confusion, depression, mania, homicidal excitement, and hysterical behaviour (Carothers, 1953; Shelley & Watson, 1936; Tewfik, 1958; Field, 1960). In some cases paranoid delusions, sometimes complicated by clouding of consciousness, lead to these states being described as schizophreniform. Lambo (1955, 1960) suggested that they resemble hysterical, epileptic and other organic states, but he also emphasised the importance of cultural factors. Haworth (1968) regards the conditions as being essentially reactive, and comes close to the Scandinavian position on reactive psychoses, which regards the occurrence of schizophreniform illnesses as being a common consequence of psychological stressors.

Rwegellera (1977), in his review of first admissions to a mental hospital in Lusaka, argued that the vast majority of these conditions were atypical presentations of affective disorder, mainly depression. While his observations must be given due weight in view of his careful approach to diagnosis based on form rather than on the content of symptoms, his observations still beg the question as to the frequency of so many atypical presentations. It may be that depression is more likely to present when it is atypical and is characterised by more bizarre and disruptive symptoms, such as hysterical or schizophreniform features.

Other factors may contribute. Assael & German (1970) argued for the conditioning effect of background cerebral dysfunction, this being a likely factor in societies where cerebral development during infancy is frequently prejudiced by protein or calorie malnutrition, or cerebral malaria. Under such circumstances there may well be tenuous cerebral control over florid affective states, and there is also a greater likelihood of hysterical phenomena manifesting themselves in states of psychic distress where cerebral integration is impoverished. Apart from that, cultural attitudes in Africa do not discourage dramatic and vigorous emotional reactions to states of psychic pain or distress, and this is undoubtedly an important factor. Confusional contaminants may reflect the frequency with which these conditions emerge against a background of low-grade physiological disturbance such as that provoked by intercurrent infections, parasitism, vitamin deficiencies, and other states commonly found in poorer societies. Indeed, Jilek & Jilek-Aall (1970), in discussing the frequency of these states in Africa, pointed to the fact that similar acute transient disturbances were well-known in Europe at the end of the nineteenth century, and were regarded by psychiatrists of that era, particularly in Germany, as being related to poor standards of medical care and general health.

Organic psychoses

As might be expected, acute brain syndromes are common in Africa, their frequency reflecting the frequency with which human beings are exposed to severe and acute disorders of physiology capable of disrupting normal brain functioning. The commoner causes of these disorders in Africa have been listed by Jilek & Jilek-Aall (1970), and discussed by German (1972). Infections, parasitic and deficiency diseases, and a wide-ranging abuse of drugs are ubiquitous to a degree long forgotten in the developed world.

The clinical features of the resulting acute brain syndromes are as described elsewhere, although hallucinations and delusions (as in any other psychosis) are coloured by local preoccupations. There does however appear to be an unusually high frequency of such acute organic psychoses in apparently healthy young adults where the provocative toxic or infectious state seems less than would be necessary to lead to such a consequence. The situation may be analogous to the ease with which acute brain syndromes can be precipitated in elderly people living in developed countries. German (1979) argued that this would be consistent with pre-existing diminution of cerebral reserve due to previous deprivation. It may be useful to consider the profile of psychotic states and psychotic reactions that occur in elderly people in developed societies as being similar to the profile of both acute psychotic reactions and acute brain syndromes occurring in younger people in developing countries. In the psychogeriatric situation stress, background reduction of efficient cerebral functions, inefficient renal and hepatic mechanisms, and social expectations are factors which influence the amorphous patterns of psychotic states. These particular African problems therefore might best be understood within some such paradigm.

Neuroses

Comment has already been made on the frequency of psychoneurotic states. Evidence suggests that they are particularly common in Africa, including rural Africa (Orley & Wing, 1979). Murphy (1976), while noting that among Western Nigerians there are no specific word labels for the various neurotic states or for the overall concept of neurosis, also pointed out that "words for emotional responses that we might classify as manifestations of anxiety or depression constitute a very large vocabulary". She also noted that most of these emotional phenomena are thought of as illnesses for which the traditional doctor has effective cures. She went on to observe that among the Yoruba of Nigeria these conditions are much more frequent than psychotic states, the ratio being approximately 12 to 1.

As seems to be usual in African society, it was those neurotic conditions with the more dramatic presentations which were first noted and put forward as peculiar to the continent. Thus hysteria (Dembovitz, 1945) and vividly described anxiety states (Vyncke, 1957) have been regarded as characteristic. The more recent studies of Orley & Wing (1979) have revealed the frequent presence of quieter neurotic states characterised by depression and anxiety, and have done so by looking at total populations rather than mental hospital populations.

The Orley & Wing study also drew attention to the frequent occurrence of obsessions in African men and women. This is a matter of great interest, since most previous authors repeatedly emphasised the great rarity of both obsessional behaviour patterns and obsessional illness in black Africans. Orley & Wing did not comment on the possible reasons for this finding, but it is consistent with the possibility that when epidemiological studies of neurotic disorder in Africa are conducted with great care and precision there will emerge evidence to suggest that emotional and psychological response patterns have a fundamental consistency irrespective of human race and culture.

There seems to be little evidence available to suggest that psychoneurotic conditions are fundamentally different in Africa, either in prevalence or form. However, and this appears to be true of any form of psychiatric or emotional disturbance, symptom content is very much a reflection of local preoccupations. These preoccupations may be unique to a family, to a village, or to a wider culture. In general, Kraepelinian systems of classification would regard content aspects of clinical pictures as having little or no relevance to diagnosis. On the other hand, psychodynamic formulations of psychiatric distress pay considerable attention to content, as do more sociological systems. It is probable that these different viewpoints are largely responsible for the confusion which sometimes seems to exist about mental illness in Africa.

Final comments

Little has been said in this review about vital and wide-ranging issues in black Africa which have an important bearing on mental illness and mental health. Factors such as drug abuse, the break-up of traditional family structures, population mobility due to political upheaval and socioeconomic shifts, and recurrent episodes of famine and other deprivations are a feature of the area. Africa has one of the largest mobile refugee populations in the world. Nor is Africa immune to those social changes which have cast a heavy shadow over the rest of the world in recent decades. Several studies testify to the alarming prevalence of alcoholism in secondary schools. Oshodin (1980, 1981) reported that 18–40% of high school students in Nigeria showed a pattern of drinking behaviour consistent with alcohol abuse. Smith (1982) has drawn attention to the rapid increase of alcoholism and alcohol-related social, health and economic problems in Third World countries, and has pointed out that there is substantial evidence to suggest that many alcohol problems can be prevented by administrative and political measures. He believes that if Third World governments were to wake up to the threat of alcohol problems, they might be able to avoid them without a huge expenditure of time, money and effort.

However, there are major problems to be addressed if mental disorders and their associated evils are to be adequately prevented, managed, or controlled in Africa. One is the difficulty of convincing governments and leaders as to the importance of these disorders and the major impact that they have on community stability, security, and development. In addition, models developed in Europe and North America for the management and control of mental disorder are transported without thought to the African setting, and this has led to the diversion of an undue amount of health resources into the establishment of medical schools and technologically advanced hospitals and the training of medical specialists. The provision of medical schools and hospitals may appeal to politicians as being tangible evidence, to an unsophisticated population, that they should be re-elected, but it is difficult to escape the conclusion that African mental health problems require something vastly different.

As a result, international policies with regard to mental health have increasingly urged the development of health services based on village health workers and other primary health care workers (World Health Organization, 1978). The logic of such a shift is unassailable. Africa lacks the wide-ranging general practice services which are a feature of European medicine, and which probably cater for 90–95% of the needs of mentally and emotionally distressed persons in Europe. Without such a buffer, specialists in mental health in Africa are faced with an impossible task, and have difficulties functioning as they have been trained to function in the new hospitals which have developed (German *et al*, 1980). The World Health Organization programme also envisages that the expansion of primary health services will be an integral part of a development directed at redressing social evils, or at supporting, through education and community resources, their many victims. Social breakdown, poverty, population mobility, famine, and drug abuse are only a few of these evils which are not only of great significance in the precipitation of mental ill health, but of even greater significance in the erosion of community and national health to a point where it becomes ludicrous to talk of health at any level. It is therefore clear that a body charged with concern about the world's health must address itself to related social problems which must be solved, or mitigated, before sophisticated health techniques can be deployed in any credible way.

Psychiatric manpower is probably relatively scarcer in developing Africa than it was twenty years ago. At the same time, social and political turmoil has increased and the number of persons seeking assistance for mental ill health has continued to rise rapidly. If the WHO goal of "health for all by the year 2000" is to be realised to any extent, then it is imperative that in most countries of the world there be a major campaign launched at a political level to encourage a much wider view of the concept of health, and those circumstances, attitudes, and structures necessary for its promotion and maintenance. Such a campaign will have many requirements; one is that decision-makers and thinkers in the Third World should be familiar with current evidence which suggests that formal mental illness is as significant a problem in the Third World as anywhere else, and indeed may be an even greater problem in terms of impact and sheer numbers.

In conclusion, the extent and nature of mental ill health throughout black Africa does not appear to be such as to suggest that psychiatric disorders are culture-bound and the prerogative of so-called advanced societies. Problems relating to mental health appear to be intrinsic to the nature of man and to reflect the impossibility of separating biological, psychological, and cultural influences. Although the 'medical model' - or perhaps more precisely the 'Western nosological model' - seems capable of adequately accounting for the nature of the majority of these African mental ill health problems, purely medical approaches are not in themselves sufficient to contain or reduce these problems. Within developing countries there is an urgent need to rethink methods of health care to take account of the realities of local demographics, socioeconomic conditions, and cultural values.

Anthropology and Psychiatry

The Role of Culture in Cross-Cultural Research on Illness*

ARTHUR KLEINMAN

To illustrate the contribution anthropology can make to cross-cultural and international research in psychiatry, four questions have been put to the cross-cultural research literature and discussed from an anthropological point of view: 'To what extent do psychiatric disorders differ in different societies?' 'Does the tacit model of pathogenicity/pathoplasticity exaggerate the biological aspects of cross-cultural findings and blur their cultural dimensions?' 'What is the place of translation in cross-cultural studies?' and 'Does the standard format for conducting cross-cultural studies in psychiatry create a category fallacy?' Anthropology contributes to each of these concerns an insistence that the problem of cross-cultural validity be given the same attention as the question of reliability, that the concept of culture be operationalised as a research variable, and that cultural analysis be applied to psychiatry's own taxonomies and methods rather than just to indigenous illness beliefs of native populations.

Anthropology and medicine enjoy a long relationship. Among the late nineteenth and early twentieth century founders of anthropology were physicians who possessed social psychological and psychosomatic orientations (e.g., W.H.R. Rivers in England, Paul Broca in France, Rudolph Virchow in Germany). Key figures in the development of psychiatry maintained a cross-cultural interest and read the relevant anthropological literature (e.g., Emil Kraepelin, Sigmund Freud, Adolph Meyer, Aubrey Lewis, to mention only a few). Similarly, leading figures in twentieth century anthropology (most notably Alfred Kroeber and Edward Sapir in the US, Bronislaw Malinowski and Meyer Fortes in England, and Claude Lévi-Strauss in France) kept up with relevant developments in psychiatry and particularly psychoanalysis. In the 1940s and 1950s, the 'Culture and Personality' school of North American cultural anthropology brought together anthropologists and psychoanalysts in research seminars and collaborative projects. Even at present, although the two fields are moving in very different directions, many anthropologists maintain strong interest in psychiatric questions and, at least in North America, a small number are members of psychiatric research units. On the other side, psychiatrists conducting international, cross-cultural and cross-ethnic studies frequently cite the writings of anthropologists, and there is even a small cadre of psychiatrists who, like myself, are trained in anthropology.

Yet, for all this cross-disciplinary interest (at least in North America), there is little evidence that anthropology exerts any significant influence in psychiatry, or vice versa. Even in cross-cultural and social psychiatry – the two subdisciplines that come the closest in problem framework to the concerns of the social sciences – anthropology is marginal: more of informal, heuristic interest than of central, substantive importance. Rarely are psychiatric trainees systematically taught about relevant anthropological concepts and findings, even where those trainees spend significant time practising in cross-cultural or cross-ethnic settings. Just as rare is the psychiatrist engaging in cross-cultural research who raises anthropological questions and findings pertinent to his enquiry. This is a harsh judgement, but I believe the facts support it: psychiatry proceeds, even or especially in centres that are non-Western or ethnic, as if anthropology did not exist, or was irrelevant to illness and care (Kleinman, 1985).

Conversely, anthropology graduate students most often go to the field to study the relationship of culture to illness or healing with hardly any systematic preparation in relevant diagnostic, epidemiological or treatment issues. Indeed, there are not a few anthropologists studying illness who seem remarkably unaware of key changes in psychiatry's data base and conceptual orientations. It is embarrassing to read anthropological accounts that provide sensitive discriminations of the heterogeneity of folk healing systems but caricature biomedicine and psychiatry.

---

*Revised version of a paper presented at the World Psychiatric Association's regional symposium, 'Psychiatry and Its Related Disciplines', Copenhagen, 1986.

This situation is, to my mind, deplorable. There are, however, heartening indications that it may improve. The argument I will advance is that much is to be gained by a robust, two-way relationship between psychiatry and anthropology; ambitious and fundamental exchange across the two disciplines could contribute in quite practical ways to the strengthening of both. In this paper I will illustrate what an anthropological orientation can contribute to psychiatry by examining four key questions that anthropology raises concerning cross-cultural and international research in psychiatry. While almost all psychiatrists are impressed by the revolutions in biochemistry and neuroscience and their transforming effects on the profession, few realise that medical and psychological anthropology have also undergone a transformation which has made anthropological questions more pertinent to epidemiological, psychopathological, and treatment concerns.

Four Anthropological Questions for Psychiatry

To what extent do psychiatric disorders differ in different societies?

An anthropological reading of the literature in cross-cultural and international psychiatry reveals a strong bias of psychiatrists toward 'discovering' cross-cultural similarities and 'universals' in mental disorder. First, this bias should not come as any surprise. Much of cross-cultural psychiatric research has been initiated from a wish to demonstrate that psychiatric disorder is like other disorders: it occurs in all societies, and it can be detected if standardised diagnostic techniques are applied. Clearly this was an interest of the WHO's International Pilot Study of Schizophrenia (1973), which expected that core symptoms of schizophrenia would cluster together in more or less the same way in Western and non-Western, industrialised and non-industrialised, societies. It should come as no surprise that this is what the IPSS found, in a non-epidemiological, clinic-based comparison that applied a template of symptoms to psychotic patients in a range of societies to identify groups of patients who seemed similar. The problem with this study is that it leaves out those patients who fail to fit the template, the very patients of greatest interest from a cultural perspective, because they could be expected to reveal the greatest amount of cultural diversity. The IPSS also found that outcome varies inversely with the social development of the society – a striking finding attesting to cultural difference, but one that has taken back seat to the emphasis on cross-cultural similarity (World Health Organization, 1979).

Following IPSS came the Determinants of Outcome Study, a similar study but one which began in an epidemiologically more rigorous manner with first-contact incidence sample of patients with psychotic disorder. Let us look in detail at a report of the findings of this study of more than 1300 cases in twelve centres in ten countries (Sartorius *et al*, 1986). It is a very important project that has been conducted with more rigour than most in the cross-cultural field, and it illustrates the divergent perspectives of psychiatry and anthropology. The authors note:

> The frequency of the use of individual ICD subtype rubrics varied from 0 to 65% of the cases in the different centers. Overall, paranoid schizophrenia was the most commonly diagnosed subtype followed by that of 'other' (undifferentiated) and acute schizophrenic episodes. However, in the developing countries the acute subtype diagnosis was used almost twice as often (in 40% of the cases) as the diagnosis of the paranoid subtype (in 23% of the cases). Catatonic schizophrenia was diagnosed in 10% of the cases in developing countries but in only a handful of cases in the developed countries. In contrast, the hebephrenic subtype was diagnosed in 13% of the patients in the developed countries and in only 4% of the patients in developing countries.

Despite this impressive evidence of cross-cultural differences, the authors conclude:

> Patients with diagnosis of schizophrenia in the different populations and cultures share many features at the level of symptomatology . . .

and

> Once the existence of broad similarities or manifestations of schizophrenia across the centers was established . . .

The authors are of course correct that they do have evidence of 'broad similarities', evidence they choose to highlight. But they also have evidence of substantial differences that they choose to de-emphasise.

Or take, as another example, the data on annual incidence of schizophrenia. Two calculations are made – one for a 'broad' diagnostic definition of schizophrenia that includes virtually all cases sampled, and another for a restrictive definition based on the CATEGO computer program class S+. For the former, the rates per 10 000 population range from 1.5 in Aarhus to 4.2 in Chandigarh's rural center. For the latter, the range narrows impressively from 0.7 in Aarhus to 1.4 in Nottingham. Sartorius *et al* discuss this change by arguing that the application of the restrictive definition does not result in loss of statistical significance owing to decreased sample size. They conclude later in the paper that there is a relatively uniform rate of incidence for schizophrenia across the ten societies. From the perspective of psychiatric epidemiology and biostatistics this may be a valid conclusion, but from an anthropological perspective it is tautological. The 'broad' sample, from the anthropological perspective, is the valid one, since it includes all first-contact cases of psychoses meeting the inclusion and exclusion criteria. The 'restricted' sample is a 'constructed' sample, since it places a template on the heterogeneous population sample and stamps out a homogeneous group of clinic cases. The restricted sample demonstrates to be sure that a core schizophrenic syndrome can be discovered among first-contact cases in widely different cultures. This is an important finding, but it is not evidence of a uniform pattern of incidence. Indeed, the restrictive sample leaves out precisely those cases that show the greatest cross-centre and cross cultural differences and therefore the ones that disclose that the pattern of incidence is not uniform. This sample is of most interest to anthropologists since it demonstrates a wide range of cultural differences. Ironically, the finding of a wider range of incidence, which is in keeping with the finding in other studies of significant variation in the epidemiology of schizophrenia world-wide, should be of most interest to those concerned with the 'biological base', because this is what would be expected of a genetically based disorder. Several other key instances could be cited in which the evidence reviewed by the WHO group discloses both important similarities and important differences, but the authors elect to focus principally on the former, namely the 'universals'.

When this outstanding group of investigators review the data on the differential course of schizophrenia across centres (with better outcome in the developing societies), they report that this finding holds up even when mode of onset (acute versus chronic) is controlled. For over 10 years this finding has been the most provocative to emerge in cross-cultural psychiatry. Readers will be disappointed, however, if they hope to learn more about its sources or implications. The authors are silent on these points, which apparently have not received detailed investigation. That is to say, the most important finding of cultural difference – arguably the single most important finding in the study – receives scant attention compared to that devoted to the findings of cross-cultural similarity. In the summary of the paper, the other findings of cultural difference in mode of onset, symptomatology, and help-seeking are de-emphasised as well.

If this were a single instance of interpretive bias in cross-cultural psychiatric research, it would be one thing: in fact, it is representative of the dominant interpretive paradigm in cross-cultural psychiatry. There is a tacit professional ideology which functions to exaggerate what is universal in psychiatric disorder and de-emphasises what is culturally particular. This view fails to acknowledge, moreover, what the evolutionary biologist knows: biology is the great source of diversity, not just of uniformity (Mayr, 1982). Had I reviewed the anthropological literature, I could have demonstrated the obverse.

A more valid interpretation of the data base emerges when the two viewpoints, both biased but in opposite directions, are reviewed together. The findings for schizophrenia, major depressive disorder, anxiety disorders, and alcoholism disclose both important similarities *and* equally important differences. Hence the first anthropological question (How do psychiatric disorders differ across cultures?) is a necessary complement to the regnant psychiatric question (How are psychiatric disorders similar across cultures?).

Indeed, for all the talk about ethnological comparisons, anthropology is essentially a field of detailed, intensive, single-culture studies in which comparisons are made by a scholarly review of the literature on other cultures (Kleinman & Good, 1985) rather than by 'controlled' cross-cultural comparisons. Hence anthropological research points to the importance for psychiatry of scholarly analysis of studies of mental illness in one culture to deepen our understanding of cultural differences: in turn it benefits from psychiatry's example of undertaking multicultural projects in which mental illness is studied simultaneously in the same methodological framework in different societies – something anthropology has not done.

I have taken the liberty to be critical of the WHO research program because of its importance and the fact that the WHO group's studies are among the most rigorous and sophisticated in the cross-cultural field. I have every reason to believe that following this initial stage of demonstrating cross-cultural universals in mental illness the WHO group will begin to correct the balance by turning to the differences, which is already beginning to happen (c.f. Marsella *et al*, 1985).

Is there a tacit model in cross-cultural psychiatric research which exaggerates the biological dimensions of disease and de-emphasises the cultural dimensions of illness?

This question is a corollary of the first question. An anthropological analysis of cross-cultural research in psychiatry shows that the model of pathogenicity/pathoplasticity comes fairly close to being a professional orthodoxy. In this revealed version of the psychiatric truth, biology is presumed to 'determine' the cause and structure of disorder, while cultural and social factors, at most, 'shape' or 'influence' the content of disorder. The classical example is paranoid delusions in schizophrenia or depressive psychosis: the biologically based disease causes the delusional thought process but the system of cultural beliefs organises the content of paranoid thinking – here as fear that the CIA is out to harm one, there as belief that the KGB is the culprit.

The widespread finding that somatic symptoms in depression and anxiety disorders play a more central role in the experience and expression of disorder in non-Western societies and among ethnic groups in the West is another informative case. Somatic amplification and hypochrondriacal focusing are seen as distinctive manifestations of a similar underlying disorder. The latter is said to be 'masked' by the former. In this stratigraphic vision, biology is bedrock, whereas psychological, and in particular social and cultural, layers of reality are held to be epiphenomenal. They need to be stripped away to disclose the 'real' disease. As for medical anthropology's distinction between illness and disease – in which illness is the patient's perception, experience and communication of symptoms, while disease is the clinician's reformulation of the problem in terms of psychiatric models – disease is taken to be 'real' and hidden by the illness, which is a cultural artifact: catatonic or somatic or hysterical manifestations of the underlying causal process. Diagnosis then becomes reductionist, the semiotic interpretation of 'signs' of disease as an entity or object out of "the blooming, buzzing confusion" of illness symptoms.

The anthropological perspective suggests an alternative model. Depression experienced entirely as low back pain and depression experienced entirely as guilt-ridden existential despair are such substantially different forms of illness behaviour with different symptoms, patterns of help-seeking, course and treatment responses that though the disease in each instance may be the same, the illness rather than the disease is the determinant factor. There is overwhelming evidence in North American society that the social and psychological components of the illness experience of chronic pain are more powerful determinants of disability and return to work than the biological abnormalities, which are usually 'real' enough (Yelin *et al*, 1980; Stone, 1984). Hence in the newer medical anthropological model, biological and cultural factors dialectically interact. At times one may become a more powerful determinant of outcome, at other times the other, but most of the time it is the interaction (the relationship) between the two which is more important than either alone as a source of amplification or dampening of disability in chronic disorder. Furthermore, that dialectic may transform the biology just as it alters social relationships (Lewontin *et al*, 1984).

The pathogenetic/pathoplastic model also does an injustice to the culture-bound syndromes. The tendency is to interpret these as illness manifestations of particular 'underlying' disease: e.g., susto is depressive disorder; semen loss syndromes are anxiety disorders; amok is brief reactive psychosis; etc. The picture is much more complex. Carr (1978, 1985) shows that amok is a final common pathway of behaviour along which are channelled various kinds of problem: acute and chronic psychoses to be sure, but also criminal behaviour without psychopathology, alcohol- and drug-induced states, and so forth. Guarnaccia *et al* (1987) and Low (1985), among others, demonstrate that *ataque de nervios* among Hispanics is not simply conversion disorder, but may be anything from a medical disease, to schizophrenia, to a culturally appropriate bereavement reaction. The anthropological model of an idiom of distress offers a more accurate mapping of the experience of culture-bound disorder, and its sources and consequences, than does the medical model. Alternatively, the demonstration of Rubel *et al* (1984) that susto is associated with higher rates of mortality indicates the necessity of combining biomedical and anthropological assessments.

What place does translation have in cross-cultural research?

Medical, including psychiatric, research often procedes as if translation were a nuisance to be quickly handled in much the same way as one controls the demographics in matched samples. For psychologists, translation is rendered a technical problem, one that can be handled through a rigorous process of translation by one set of bilingual key informants, back-translation into the original language of the psychometric instrument by another set of bilingual informants, negotiation of the differences, and testing of reliability of the instrument, when compared with other measures of the same phenomena that have already been used in the recipient society, and when used by different groups of investigators. But, for the anthropologist, translation is neither of nuisance value nor a strictly technical problem; it is the very essence of ethnographic research. For the anthropologist, translation of findings into terms and categories that allow for cross-cultural comparison is the final, rather than as in psychiatric research, the first step. Therefore, the anthropological contribution to psychiatry in this area is to model a much more rigorous, systematic and contextual approach to translation. Let us examine a few examples.

Most assessment instruments are developed in a vernacular that is quite difficult to translate into other languages. North American diagnostic instruments, for example, employ the terms 'feeling blue' or 'feeling down' to assess dysphoria. A strictly lexical translation of these terms is meaningless in most non-Western languages. Manson *et al* (1985) translated the NIMH-sponsored Diagnostic Interview Schedule (DIS) into Hopi, an American Indian language. One DIS item combines the concepts of guilt, shame, and sinfulness. Twenty-three bilingual Hopi health care professionals clearly distinguished each of these concepts from the others and indicated that three separate questions were required to avoid confounding potentially different responses. Kinzie *et al* (1982) discovered much the same thing in developing a Vietnamese language depression scale. They found that 'shameful and dishonored' but not 'guilt' discriminated depressed from non-depressed Vietnamese Americans.

Gaviria *et al* (1984), working with a translation of the DIS in Peru, detected five kinds of problem in its validity that offer a broader sense of problems in translation. First, by content validity they meant that the content of instruments must be relevant in the culture into which the instrument is translated. Thus, many of the substances in the substance abuse section of DIS were unavailable in Peru; yet coca paste, a major drug in Peru, did not appear in DIS. Secondly, semantic validity requires that the words used in the original DIS and the new instrument have the same meaning, a problem we have already reviewed. Thirdly, technical validity refers to societies where languages are not written (or at most by an elite), schooling is limited and rates of illiteracy are high. In this context, the process of answering a questionnaire is foreign and one may elicit answers that represent a misunderstanding of intentions more than an accurate reflection of affect or thought. Fourthly, criterion validity measures whether responses to similar items relate to the same normative concept in two cultures. The presence of culturally consonant hallucinations among American Indians undergoing uncomplicated bereavement is normative in these tribal societies but not so in the broader North American culture. Assessment of hallucinations among American Indians must take account of this alternative norm. Fifthly, conceptual validity requires that responses to an interview relate to a theoretical construct within the culture. Neurasthenia is a key popular concept of disorder in China but no longer forms a coherent category for most North Americans (Kleinman, 1986). For a research interview to be conceptually valid in China, it would need to operationalise this category, not simply list its symptoms. In their entirety, several symptom check-lists include items that appear in locally salient syndromes like neurasthenia. By not organising these into operationalised syndromal clusters, the symptom check-lists fail to elicit subjects' responses.

Intra-cultural diversity makes the process of culturally meaningful translation even more complex. Canino *et al* (1987) found that in using the Spanish language version of the DIS developed at the University of California for use with Mexican Americans in a study of Puerto Ricans, they had to alter 67% of the items to adapt the instrument to the colloquial Spanish spoken by Puerto Ricans.

To adequately assess cultural differences, it is essential to translate local idioms of distress and add them to standard questionnaires. This may seem obvious, but it is not routinely done. For example, Ebigbo (1982) has demonstrated that Nigerian psychiatric patients have a unique set of somatic complaints which are not represented in standard symptom-screening scales. In a number of African cultures, anxiety is expressed as fears of failure in procreation, in dreams and complaints about witchcraft. To adequately evaluate psychopathology in these settings, those common idioms must be assessed. The most impressive attempt to take translation into account in a psychiatric epidemiological study is the study by Manson *et al* (1985) of depressive disorder among Hopi. They built an instrument with two components: a very carefully translated version of the DIS that met each of the issues reviewed above, and an operationalised list of symptoms and categories from Hopi indigenous nosology that had a prima facie resemblance to depression.

From an anthropological perspective, the problem of translation is that there may exist objective and universal referents for a term like headache which enables a process of searching for semantic equivalence. But, as Good *et al* (1986) note,

> In general, however, the referents of symbols – i.e., their meaning – are aspects of a culture or a life world, not objects outside of language through which language obtains meaning. 'Heart discomfort' for Iranians is not the equivalent of 'heart palpitations' for Americans; it does not *mean* the same thing (c.f. Good, 1977). It is a symbol which condenses a distinctive set of meanings, a culture-specific semantic network . . . Complaints of feeling impure in India refer to a semantic domain of profound cultural significance, one which expresses distinctions in caste, sexuality and social hierarchy: there is no equivalent among North Americans.

The Chinese term *huo qui da* refers to a feeling of heat rising from abdomen into the chest. It is based on the traditional Chinese medical concept that *qi* (vital energy) can be excessively hot and thereby cause symptoms. But it also metaphorically conveys the idea of an irascible personality. This metaphoric meaning would not be tapped by standard research instruments or translating practices: yet it is important for psychiatric assessment. Fear of obesity and of houseboundness in the USA does not carry the same meaning in South Pacific, African and Asian societies. Ideally, clinical care should provide a kind of culturally sensitive mini-ethnography of a patient that encompasses these cultural and personal metaphors. How to achieve this in a research project is a major problem. But the presence of such information can make a great difference in the validity of cross-cultural research findings.

Does the standard approach to cross-cultural research in psychiatry commit a 'category fallacy'?

A category fallacy (Kleinman, 1977) is the reification of a nosological category developed for a particular cultural group that is then applied to members of another culture for whom it lacks coherence and its validity has not been established. Shweder (1985), for example, suggests that among traditionally oriented rural populations, in many non-Western societies, the phenomenology of depressive disorder is better captured by local syndromes of 'soul loss' than by Western existential categories. A psychiatrist from such a society could operationalise the concept and symptoms of soul loss in his society, then organise them into a questionnaire, establish its reliability for use in his society, then translate its items into English, have them back-translated into the original language by another team of bilingual mental health workers, adjust the questionnaire for semantic equivalence, measure its reliability in the hands of native English-speaking clinicians, and apply the questionnaire to a stratified sample of an urban, middle class North American population in an epidemiological survey. He would come up with prevalence data. But would such data be valid, inasmuch as the disorder soul loss has no coherence for middle class North Americans? Obeyesekere (1985) has illustrated the same problem by conjuring up a South Asian psychiatrist studying semen loss syndrome among North Americans. This is a category fallacy, and it occurs routinely in cross-cultural psychiatric research, only the other way around, by the imposition of Western categories in societies for which they lack coherence and validity.

Dysthymic Disorder in DSM–III (or neurotic depression in ICD–9) is a possible example. It may hold coherence in the more affluent West, but it represents the medicalisation of social problems in much of the rest of the world (and perhaps the West as well), where severe economic, political and health constraints create endemic feelings of hopelessness and helplessness, where demoralisation and despair are responses to real conditions of chronic deprivation and persistent loss, where powerlessness is not a cognitive distortion but an accurate mapping of one's place in an oppressive social system, and where moral, religious and political configurations of such problems have coherence for the local population, but psychiatric categories do not. This state of chronic demoralisation, furthermore, is not infrequently associated with anaemia and other physiological effects of malnutrition and chronic tropical disorders that mirror the DSM–III symptoms of Dysthymic Disorder. In such a setting, is the psychiatrist who is armed with a local translation of DIS or other clinical instruments devised for Western populations in order to study the prevalence of Dysthymic Disorders any different from the Nuer psychiatrist studying soul loss in midtown Manhattan? Great care must be exercised in the application of this diagnostic category to assure that its use is valid.

For the psychiatric epidemiologist, determining a 'case' of a disorder from a person with distress but no disorder is the crucial dilemma. In making that distinction, taxonomy becomes entangled in its own decision rules. For patients with loss of energy due to malaria, appetite disturbance owing to the anaemia of hookworm, sleeplessness associated with chronic diarrhoeal disease, and dysphoria owing to poverty and powerlessness, the difference between 3 and 4 'vegetative' complaints is the difference between becoming a case of depression as a disease or being an instance where depression is a socially caused type of human misery. DSM–III was not created with such problems in mind, but it is applied in such settings. The result is as distorted a view of pathology as it is an inappropriate use of diagnostic categories.

Conclusion

Again, we confront the problem of validity. In a recent major statement on psychiatry, McHugh & Slavney (1986) define reliability as the "verification of observations" and validity as the "verification of presumptions". These influential American psychiatrists further define reliability as "the consistency with which one can make an observation". They claim that

> the reliability of some psychiatric observations is high. This indicates that psychiatrists can determine whether a patient does or does not have abnormal mental states such as delusions and hallucinations.

Reliability, following their own useful definition, indicates no such thing. It indicates only that the measurement of the observations is consistent. It does not tell us if the observations are valid: that is, whether a patient does or does not have an abnormal mental state. Here is an example. Ten psychiatrists trained in the same assessment technique and diagnostic criteria who are asked to examine 100 American Indians shortly after the latter have experienced the death of a spouse, a parent or a child may determine with close to 100% consistency that those individuals report hearing, in the first month of grieving, the voice of the dead person calling to them as the spirit ascends to the afterworld. That is reliability of observation. But the determination of whether such reports are a sign of an abnormal mental state is an interpretation based on knowledge of this group's behavioural norms and range of normal experiences of bereavement. Hearing the voice of the dead is an expected experience in bereavement among a number of American Indian tribal groups; this experience does not portend psychosis or other abnormal complications of bereavement. Thus, to interpret these normal experiences as 'hallucinations' with all the significance of pathology that term connotes is reliable but *not valid*.

For McHugh & Slavney, and many psychiatrists who are less theoretically sophisticated, observations are direct representations of reality. A word, hallucination, points to an empirical reality – i.e., abnormal mental state – in the real world. For the anthropologist, the word is a sign that signifies a meaningful phenomenon in a practical, day-to-day world mediated by a cultural apparatus of language, categories, taxonomies, and different hierarchies of relevance. In such a local world of culture, interpretations are always judgements whose reliability may be determined by consistency of measurements but whose validity needs to be established through *understanding* that particular cultural context. Validation is not simply verification of concepts used to explain observations. Rather it is as well verification of the meaning of the observations in a particular social system (a particular village, town, research laboratory, or clinic). Perception is a process of observing *and* interpreting in a practical situation guided by concerns of relevance influenced by human interests. Anthropologists would not say that clinical assessment cannot be validated, but that such validation is at heart an ethnographic enterprise. Thus, to avoid a category fallacy, cross-cultural research must be grounded in the local ethnographic context. This simply does not take place in most psychiatric studies.

I have tried to illustrate through these four questions some of the practical contributions of an anthropologically informed viewpoint to cross-cultural psychiatric research. Perhaps the most availing role for anthropology in relation to psychiatry is to continually remind us of these dilemmas, to challenge the hubris in our attempts to medicalise the human condition, to encourage humility in the face of alternative cultural formulations of human problems, which for anthropologists are different visions of the world rather than reflections of 'ignorance', and to make us uncomfortable with our taken-for-granted professional categories and the tacit 'interests' they represent.

When depression is the source of anxiety...
PROTHIADEN
Dothiepin Hydrochloride B.P.
restores peace of mind

Differential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female patients will usually present with symptoms of both. The potential risks of an inappropriate choice of treatment for these patients can often be a cause for concern.

Prothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this concern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left untreated.

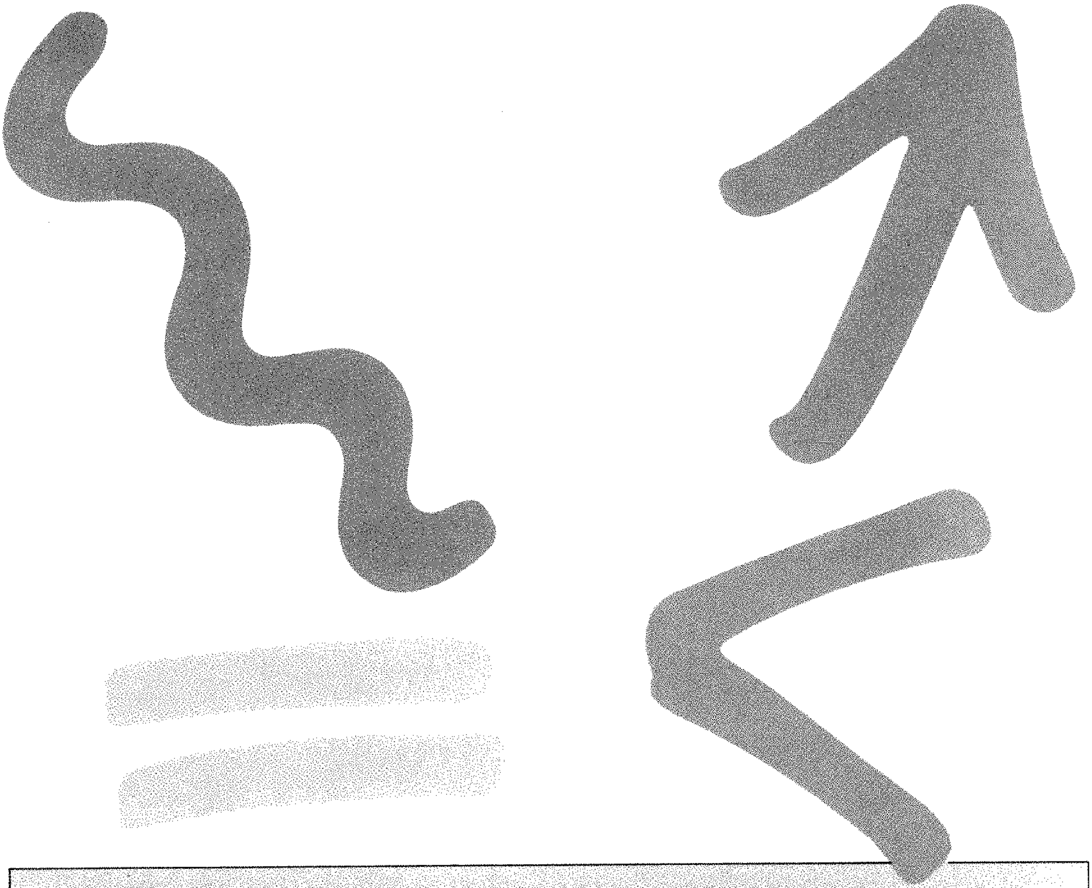
So, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well as that of your patients.

PRESCRIBING INFORMATION

Presentation: Prothiaden is Dothiepin Hydrochloride B.P. an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 75mg £4.00 as at 1st Nov. 1986. **Product Licence Numbers:** PL0014/5941. PL0014/0209. The Boots Company PLC, Nottingham, England. Further information available on request.

THE DEPIXOL

cis(Z)-flupenthixol decanoate



DIFFERENCE

= Proven antipsychotic effect (1-7)

↑ Restores mood (1-3) **∿ Dosage flexibility** **< Cost-effective therapy (8)**

PRESCRIBING INFORMATION

Depixol Injection and Depixol-Conc. Injection contain cis(Z)-flupenthixol decanoate, 20mg per ml and 100mg per ml respectively, in thin vegetable oil.
Indications Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy.
Dosage and Administration By deep intramuscular injection, 1-2ml every 2-4 weeks, to a maximum of 400 mg weekly. Children. Not recommended for children.
Side Effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson drug treatment.
Contra-indications Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusional, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy.
Further Information Overdosage should be treated; (a) by anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur, (b) by sedation (with benzodiazepines) in the unlikely event of agitation or excitement, (c) by noradrenaline in saline intravenous drip if the patient is shocked.
Package Quantities & Basic NHS Prices Boxes of 10 x 20mg (1ml) £15.53, 10 x 40mg (2ml) £25.99, 10 x 100mg (1ml) ampoules £59.53, 5 x 20mg and 5 x 40mg syringes £8.51 and £13.74, 1 x 200mg (10ml) and 1 x 500mg (5ml) vials £14.74 and £28.27
PL Nos 0458/007/0015 PA Nos 115/1/1,2,3,5,6,7,8.

Calcium-Activated Potassium Conductance

An Alternative to the Dopamine Hypothesis of Neuroleptic Action?

TIMOTHY G. DINAN

Neuroleptics are structurally a heterogenous group of compounds which possess antipsychotic activity. They increase dopamine metabolites by blocking dopamine receptors and enhancing presynaptic turnover. This forms the cornerstone of the dopamine hypothesis of neuroleptic action, which is supported by wide-ranging behavioural, physiological and biochemical studies. It is, however, clear that neuroleptics are far less specific for the dopamine receptor than was previously considered. They influence a range of neuronal activities, including calcium-activated potassium conductance, which governs the rate of action potential generation by many neurones. Recent physiological studies indicate that all commonly used neuroleptics alter calcium-activated potassium conductance in central neurones, in concentrations similar to those achieved clinically. An adaptive increase in calcium-activated potassium conductance mechanisms in key sensory processing neurones would render the psychotic patient less susceptible to bombardment by environmental stimuli. This action may explain in part the therapeutic effect of neuroleptics.

Neuroleptics are structurally a heterogeneous group of compounds which possess antipsychotic activity (Snyder *et al*, 1974). More than 20 years have passed since their capacity to increase dopamine (DA) metabolites, by enhancing the presynaptic turnover of DA, was demonstrated. Carlsson & Lindqvist (1963) observed that both chlorpromazine and haloperidol stimulate the accumulation of o-methylated metabolites of DA and also noradrenaline (NA). The authors postulated that these antipsychotic drugs act by blocking DA and NA receptors. A feedback activation was suggested as the mechanism underlying the acceleration of agonist synthesis. The work had a major intellectual impact and since then a vast literature has developed examining further the DA hypothesis of neuroleptic action.

Amphetamine is known to produce a paranoid psychosis in many respects indistinguishable from schizophrenia (Connell, 1958), and the stereotypic behaviour induced in rats by amphetamine has been advocated as an animal model of schizophrenia (Randrup & Munkvad, 1974). This latter behaviour pattern is claimed by Iversen (1978) to be due to overactivity of DA neurones and to be abolished when such neurones are selectively destroyed by the neurotoxin 6-hydroxydopamine or when postsynaptic receptors are blocked with neuroleptics. The potency of this response correlates highly with the rank order of neuroleptics in terms of clinical efficacy.

A high correlation ($r = 0.95$) has been found between the stimulating action of neuroleptics on striatal DA synthesis and their apomorphine antagonist action (Carlsson, 1978). Apomorphine is a powerful DA agonist and the fact that the ED_{50} values (amount of drug required to produce a 50% maximal response) in both cases are approximately equal, suggests similar affinities for receptors. Together with this, X-ray crystallographic studies indicate that chlorpromazine in its preferred conformation can be superimposed on DA and NA, while those phenothiazines lacking antipsychotic action are less liable to assume the conformation. This finding by Snyder *et al* (1974) provides a molecular mechanism by which phenothiazines can block DA receptors.

Further biochemical support

When DA receptors are labelled with ^{3}H-DA, the relative potency of phenothiazines against this receptor parallels their antipsychotic potency (Seeman *et al*, 1976). However, this high correlation is not maintained when the butyrophenones are tested. Snyder *et al* (1974) investigated the affinities of a wide range of phenothiazines and butyrophenones in competing for ^{3}H-haloperidol binding to the DA receptor. Spiroperidol, which is the most potent antagonist of DA-mediated behaviour in animals, was found to be the most potent inhibitor of ^{3}H-haloperidol binding.

It has five times greater affinity for this receptor than fluphenazine and a 40-fold greater affinity than chlorpromazine. Overall, a high correlation can be established between the molar pharmacological potencies of various neuroleptics and their affinities for the ^{3}H-haloperidol binding sites. The Johns Hopkins' group postulate that the DA receptors exist in two states, an agonist and an antagonist (Creese *et al*, 1975). This helps explain why DA agonists are over 50 times more potent in competing with ^{3}H-DA than ^{3}H-haloperidol for binding, while the reverse is true for antagonists.

Kebabian *et al* (1972) found that when various phenothiazines are compared, their potency as inhibitors of DA-stimulated cAMP formation is similar to their *in vivo* potencies as antipsychotics. The authors postulated that the postsynaptic actions of DA were mediated by a DA-sensitive adenyl cyclase, and that this enzyme activity correlates with the post-synaptic effects of DA. However, butyrophenones and diphenylbutylpiperidines have been shown to be less potent than chlorpromazine as inhibitors of adenyl cyclase (Iversen, 1975). The most potent butyrophenone spiroperidol is weaker than haloperidol or chlorpromazine in inhibiting DA-sensitive adenyl cyclase, while sulpiride, a benzamide derivative, is devoid of such activity. It now seems clear that there are at least two types of DA receptor: the D-1 type, which enhance adenyl cyclase activity, and the D-2 type, which either decrease or have little effect on cAMP (Cross & Owen, 1980). High affinity binding sites for ^{3}H-haloperidol correspond to the D-2 receptor, while high affinity binding sites for ^{3}H-flupenthixol identify the D-1 adenyl cyclase linked receptor. The DA hypothesis can easily adapt to the fact that there is more than one type of DA receptor and that neuroleptics vary in their potency at a single subtype of receptor. Thus Iversen's (1975) finding that butyrophenones are less potent than chlorpromazine as inhibitors of adenyl cyclase is accommodated.

Physiological support

Direct physiological evidence to support the DA hypothesis was provided by Bunney *et al* (1973). They found that iontophoresed DA on dopaminergic zona compacta neurones of substantia nigra produces a powerful inhibition which is abolished by neuroleptics administered either systemically or iontophoretically. When neuroleptics are given alone they significantly increase the rate of neuronal firing by blockade of the DA autoreceptor. Similar results have been reported for postsynaptic DA receptors. Recordings from septal neurones, for instance, have demonstrated that neuroleptics block DA-induced but not NA-induced inhibition (Bunney & Aghajanian, 1978). Further physiological evidence is provided by the fact that intravenous amphetamine decreases the firing of substantia nigra neurones but firing is returned to normal by chlorpromazine (Graham & Aghajanian, 1971).

Arguments against the DA hypothesis

It is now clear that neuroleptics are far less pharmacologically specific for the DA receptor than was previously thought. There is abundant evidence to indicate that they alter a wide spectrum of neurochemical activities. Chronic haloperidol, for instance, increases ligand binding not only to DA receptors but also serotonin and to a lesser degree alpha-noradrenergic receptors in the cerebral cortex (Mueller & Seeman, 1977). These latter changes in noradrenergic receptor binding are associated with profound alterations in the physiology of the noradrenergic nucleus locus coeruleus (Dinan & Aston-Jones, 1984, 1985). In fact, the affinities of many neuroleptics in competing for WB-4101 binding are similar to those of the classic alpha-antagonists phenotolamine and phenoxybenzamine (Peroutka *et al*, 1977). Not only can neuroleptics alter monoaminergic systems other than those which use DA as a transmitter, but there is also evidence to demonstrate their effects on cholinergic (Sherman *et al*, 1978), peptidergic (Somoze, 1978) and amino-acidergic (Perry *et al*, 1979) transmission.

Further arguments against the DA hypothesis have also been put forward. It must be remembered, for instance, that the number of dopaminergic neurones in the mammalian brain is relatively small and largely confined to the brainstem (Ungerstedt, 1974). Although these neurones clearly influence those at a cortical level, it has been argued that a disease of higher cognitive functioning such as schizophrenia must involve neurones at the highest level and not simply reflect a dysfunction of brainstem neurones, irrespective of how highly arborised they might be (Dinan, 1984). If such is the case, it seems unlikely that the modification of dopaminergic function would significantly influence the psychic processes involved in schizophrenia and thus adequately account for the antipsychotic action of neuroleptics. The fact that amphetamine psychosis closely resembles paranoid schizophrenia is regarded as strong evidence for implicating DA with the psychopathology of schizophrenia (Iversen, 1978); however, there has been little in-depth investigation of amphetamine action on extra-monoaminergic systems, which might also conceivably mediate the psychic effects of amphetamine. The bluderbuss lesioning of DA neurones abolishes the stereotypic behaviour produced by amphetamine in rats (Iversen, 1978), clearly implicating DA in stereotypic behaviour, but obviously not negating possible non-dopamine actions of amphetamine.

Neuroleptics and calmodulin

The potent action of butyrophenones and phenothiazines as calmodulin antagonists has been described (Weiss & Levin, 1978). Calmodulin plays a pivotal role in mediating the second messenger actions of calcium within the neurone, including the activation of a variety of enzyme systems (Stoclet, 1981). The piperazine phenothiazine, trifluoperazine, has been shown not only to be a potent calmodulin antagonist but also to reduce inward calcium currents in neurones (Chapman & Neher, 1984). Together with other neuroleptics, it depresses platelet aggregation induced with platelet-activating factor, which Levy (1983) indicates is mediated by a calcium/calmodulin mechanism. Studies on the diphenylbutylpiperidines such as pimozide indicate their capacity to inhibit nitrendipine binding to the verapamil/prenylamine class of calcium channel (Gould *et al*, 1983). They also inhibit potassium-induced calcium-dependent contractions of rat vas deferens (Gould *et al*, 1983).

Calcium-activated potassium conductance

Many neurophysiologists are actively engaged in a study of Ca^{+2}-activated K^+ conductance mechanisms in a wide variety of neurones. This conductance is important in governing the rate of action potential generation by a neurone and thus the rate of transmitter release (for review see Meech, 1978). The process begins with the opening of voltage-gated Ca^{+2} channels, resulting in the movement of Ca^{+2} inward. This Ca^{+2} together with that mobilised within the cell brings about the opening of K^+ channels, probably acting via an intermediate calmodulin-like protein. The K^+ moves along its electrochemical gradient, causing a hyperpolarisation of the membrane, which can be sustained, in many cases, for several seconds. The mechanism thus plays an important role in determining the rate of information processing by an individual neurone and in modulating the signal transmitted by the neurone.

Recent work both on the noradrenergic nucleus locus coeruleus (Dinan & Aston-Jones, 1984, 1985; Dinan, 1986) and the hippocampal pyramidal CA1 neurones (Dinan *et al*, 1987) indicates that neuroleptics alter Ca^{2+}-activated K^+ conductance. When acutely administered, those neuroleptics effective as antipsychotics depress the slow afterhyperpolarisation seen in hippocampal CA1 neurones. This afterhyperpolarisation is mediated by a K^+ conductance which is Ca^{+2}-dependent. In the locus coeruleus, haloperidol depresses both orthodromic- and antidromic-induced poststimulus inhibition, which is again mediated by a similar conductance. Dinan & Aston-Jones (1985) have shown that chronic haloperidol treatment results in the inactivation of many locus coeruleus neurones, rendering them less sensitive to incoming stimuli. White & Wang (1983), working on zona compacta neurones of the substantia nigra, report similar findings.

Defective filtration in schizophrenia

Broadbent (1958, 1971, 1977) has postulated a defect in the perceptual filtration mechanism in schizophrenia, which results in the individual being bombarded by environmental stimuli, overloading his cognitive processing capacity. Several studies support this delineation of specific defects in the filtering phase of information processing. Broen & Nakamura (1972) found that chronic non-paranoid schizophrenics demonstrate a more restricted range of sensitivity toward peripheral sensory channels than do acute paranoid schizophrenics or normal subjects. They also found that schizophrenics perform significantly less well than controls on span-of-apprehension tests when irrelevant noise is present, but no differences are noted when there are no irrelevancies. Schizophrenics also perform poorly when tasks which involve switching attention between stimulus modalities are employed, or in tests of discrimination shifts (Kristofferson, 1967).

The acute antipsychotic actions of neuroleptics, together with their long-term prophylactic effects, may partly be explained in terms of rectification of a defective perceptual filter. As Ca^{+2}-activated K^+ conductance is an important processing mechanism for many sensory input neurones, it provides a key neuronal site for altering the filtration of environmental and internal sensory information. For example, some visual system neurones rely heavily on such a conductance for processing information (Llinas & Lopez-Barneo, 1983). An adaptive increase in Ca^{+2}-activated K^+ conductance in such neurones, in the weeks following commencement of neuroleptic treatment, would render the individual less susceptible to bombardment by environmental stimuli. We know for instance that neuroleptics enable schizophrenics to withstand greater levels of expressed emotion from the environment without breakdown (Brown & Birley, 1968; Leff & Wing, 1971).

Crow *et al* (1976) have provided a concise summary of the DA hypothesis:

> Since many behavioural effects of the amphetamines are due to increased central DA release and since most neuroleptic compounds are blockers of central DA receptors, the symptoms of schizophrenia may be due to abnormal increase in central DA release, and the effects of this increase are diminished by partial blockade of the receptor site.

The hypothesis so stated is clearly heavily influenced by our present understanding of the aetiology of Parkinson's disease and does not adequately explain how an increase in DA might produce the intriguing psychopathology of schizophrenia. The present hypothesis is not implying that schizophrenia is due to underactivity of Ca^{+2}-activated K^{+} conductance mechanisms in central neurones. It simply states that schizophrenics process information from their environments inappropriately and one site at which pharmacological manipulation might alter such aberrant processing is at the level of Ca^{+2}-activated K^{+} conductance mechanisms in sensory input neurones. The theory takes the focus from the receptor site and directs it on the neurone as an information processing unit.

ining 50mg fluvoxamine maleate, imprinted with 'Duphar 291'. Pack of 60 tablets, basic NHS price
0. **Uses:** Treatment of those affective disorders characterised by persistent low mood, impaired
omotor activities and psychosomatic complaints. **Dosage and Administration:** The tablets should
wallowed without chewing and with water. Adults: The effective daily dose usually varies between
g and 200mg and should be adjusted to the individual response of the patient up to a maximum of
g. The minimum recommended starting dose is 100mg given in the evening. A total daily dosage in
s of 100mg should be given in divided doses. Elderly: The same dosage regimen may be utilised in the
ly as in the general population. Children: There are insufficient data to recommend the use of Faverin in
en. **Contra-indications, Warnings, etc:** Faverin should not be given together with or within two
s of terminating treatment with monoamine-oxidase inhibitors. Patients with hepatic or renal
iciency should begin treatment with a low dose and be carefully monitored. Faverin has no effect on
omotor skills associated with driving and operating machinery. However, in combination with alcohol
impairment may be seen. Use in pregnancy and lactation: There has been little human use but there
een no adverse animal evidence. Avoid in pregnancy and in nursing mothers if a better known and safer
ative is available, although safety in pregnancy is likely. Interactions with other drugs: In interaction

Faverin. Care should be taken when Faverin is prescribed to patients already receiving propran
warfarin as the dose of these drugs may need to be lowered. No interactions were seen with digoxin
atenolol. **Side-effects:** The commonest symptom observed with Faverin administration is nause
usually diminishes early during the course of treatment. Other treatment emergent symptoms r
during clinical studies were somnolence, constipation, agitation, anorexia and tremor. Other reported
are often associated with the illness and their incidence in controlled trials is comparable
experienced with placebo. Faverin may cause a decrease in heart rate. During treatment, limited ch
repolarization were observed in the ECG, but no causal relationship could be demonstrated. The inci
postural hypotension was similar to that seen in patients treated with placebo. Treatment of overdos
specific antidote is known. The stomach should be emptied as soon as possible after tablet inges
symptomatic treatment should be given. The use of medicinal charcoal is also recommended. **P**
Quantities 50mg tablets: available in packs of 60 (3 strips of 20 blister-packed tablets). **Product L**
Number 50mg tablets: 0512/0070. Further information is available from: Duphar Laboratories
Duphar House, Gaters Hill, West End, Southampton SO3 3JD. Tel: Southampton (0703) 472281.

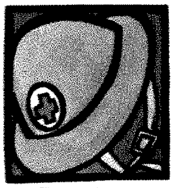
FAVERIN®
fluvoxamine

Highly Selective 5-HT Reuptake Inhibitor

So what has Lilly ever done for Britain?



Well, where should we start?

The Second World War seems as good a place as any. By 1942 around one third of the production capacity of our newly-built Basingstoke factory was devoted to producing medicines for Britain's armed forces.

From foot powders to burn treatment, products manufactured by Lilly played their part in Britain's war effort.

Today we are contributing more than ever to Britain.

Our Part in Building Basingstoke

In 1939 we opened our first manufacturing plant in Britain, at Basingstoke. In those days the town had a population of less than 20,000. Today it is a busy commercial centre of 90,000 people.

As one of Basingstoke's biggest and longest-established employers, we are proud of our role in the town's growth and current success.

Just the Job for Liverpool

At Speke on Merseyside, our antibiotics processing plant provides much needed jobs for 900.

In fact, our Speke General Manager was recently awarded an OBE for his 'outstanding contribution to alleviating the problems of Merseyside.'

Add in our other UK operations, including our research centre in Surrey, and Lilly Industries Limited employs over 2,000 people throughout Britain.

The Health of the Nation

Leaving aside our contribution to the economy's well-being, we also do a considerable amount for the nation's health.

As one of the world's leading pharmaceutical companies, we have discovered and developed numerous important drugs.

An Indispensable Discovery from Lilly

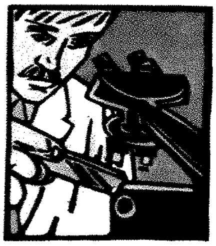
It was Lilly who pioneered the Vinca Alkaloid group of compounds. These are widely used in Britain in the treatment of childhood leukaemia and are described by the Oxford Textbook of Medicine as 'indispensable.'

Thanks in part to this discovery, a condition that once almost always condemned young sufferers to death now has a vastly improved prognosis.

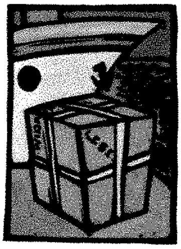
Then there was our work in the development of oral antibiotics. Before their introduction, administering antibiotics was a laborious and costly process. Expensive for the NHS and painful for the patient. With our help, the discomfort of both parties has been considerably lessened.

More recently, in 1982, we introduced genetically engineered human insulin manufactured in our plant in Speke. The benefit to patients with diabetes in Britain and around the world is unquestionable.

Where Research Becomes Reality



The success of our products is based, to a great extent, on research. UK research personnel located at our Erl Wood Research Centre in Surrey have contributed greatly to many of our worldwide projects, a prime example of Britain's expertise in the pharmaceutical field.



Exporting to the World

Lilly Industries Limited ranks among Britain's top exporters. Products manufactured here are distributed around the world, netting millions for Britain's balance of payments each year.

And what of profits? As an American company, do all the financial benefits wing their way back across the Atlantic? Not at all.

Investing in Britain

Our investment in Britain now tops over £140 million. In the last five years alone we have ploughed back £80 million. What is more, with our continued commitment to innovative pharmaceutical fields such as rDNA technology, we'll be spending a lot more in Britain in the next few years.

Employment, economic growth, investment and expertise. Just a few of the things an American pharmaceutical company has done for Britain.

Commentary on Dinan's Hypothesis*

LESLIE L. IVERSEN

Dinan's paper seeks to question the validity of the now widely accepted hypothesis that neuroleptic drugs of various different chemical categories all act by a common mechanism, namely by blockade of dopamine receptors of the D2 type in brain (for review see Creese *et al*, 1978, 1983; Iversen, 1985). While it is always refreshing to re-examine existing scientific dogma, his criticisms did not appear to me to be very substantial. Having quite fairly reviewed the evidence in favour of the "dopamine hypothesis" for neuroleptic drug action, Dinan summarises his reasons for questioning it. He points out that many neuroleptic drugs have potent actions on a number of other targets, apart from the dopamine receptors in brain. This is indeed so, and the archetypal compound, chlorpromazine, has a particularly rich spectrum of pharmacological activity, being a potent antagonist of serotonin (5-HT_2) receptors, α-adrenoceptors, and histamine (H1) receptors in brain and other tissues. Other neuroleptics also have potent actions on a number of other systems. Indeed, if one were to have studied only chlorpromazine, it is doubtful whether the "dopamine hypothesis" could ever have been developed. The strength of this hypothesis lies in the fact that of all the diverse pharmacological actions which different neuroleptic drugs exhibit, this is the only action that is common to *all* neuroleptic compounds. Furthermore, in a large group of neuroleptics, which differ widely in potency (doses in man ranging from 1 mg/day to almost 1000 mg/day), the potencies of these drugs as dopamine (D2) antagonists correlate significantly with their clinical potencies. Attempts to make such correlations with any other known pharmacological properties of these drugs fail to show significance (Creese *et al*, 1978, 1983).

To suggest, as Dinan does, that "a disease of higher cognitive functioning such as schizophrenia must involve neurones at the highest level and not simply reflect a dysfunction of brainstem neurones . . . " is simple prejudice, not based on any scientific facts. In any case, dopamine neurones do exist in the limbic forebrain, and they send important projections to certain areas of frontal cortex.

Dinan's alternative proposal to explain how neuroleptic drugs act is that they block a particular ionic channel in neuronal membranes, a calcium-activated potassium conductance. This may be related to the known property of some neuroleptics to act as antagonists of the calcium–calmodulin system. The new findings reported by Dinan *et al* are original and of interest, showing that haloperidol, chlorpromazine and trifluoperazine have this effect

*Commentary on preceding paper by T. G. Dinan.

when added *in vitro* to rat hippocampal slice preparations. However, these are only three of the many neuroleptics that exist; to suggest that this is a proven action for "all commonly used neuroleptics . . . in concentrations similar to those achieved clinically" (as Dinan states in his summary) is to extrapolate wildly beyond the available experimental results. To test whether there was any correlation between this effect and neuroleptic activity, a much larger number of compounds would need to be tested, including pairs of compounds such as (+) and (−) butaclamol and (α) and (β)-flupenthixol, where in a pair of isomers it is known that only one compound possesses neuroleptic activity. The question of drug concentration is also relevant, since the actions described by Dinan *et al* are elicited only at micromolar concentrations, much higher than those found free in body fluids clinically (although larger amounts of neuroleptic may be present in plasma tightly bound to protein), and also 100–1000 times higher than the concentrations required for dopamine receptor blockade.

The author goes on to relate these new findings to Broadbent's hypothesis of a defect in perceptual filtering in schizophrenic illness. The neural mechanisms involved in such a phenomenon, however, are quite unknown, so it is impossible to relate this is in any way to changes in ionic mechanisms as suggested.

Overall, Dinan seems to fall into many of the familiar pitfalls that have lured others in this field, and his arguments failed to convince me. It is inherently difficult to explain the actions of psychopharmacologically active compounds in terms of a molecular mechanism, but the "dopamine hypothesis" for explaining the actions of neuroleptics comes close to this, and has been one of the major achievements of research in this area in recent years.

The Dopamine Hypothesis Survives, but There Must Be A Way Ahead*

T. J. CROW

Karl Popper has taught us that no hypothesis can be regarded as proved – merely as having survived the most stringent tests which have so far been devised. Dinan makes a further attempt to overthrow the dopamine hypothesis of the mechanism of the antipsychotic effect, and provides an alternative suggestion. As one time critic and later advocate of the theory, I think he underestimates its explanatory power and capacity for survival. I doubt that his alternative yet poses a serious challenge. I propose below a second (and perhaps more idiosyncratic) alternative. I do not claim it yet has the explanatory power of the dopamine theory, but I think it generates some new approaches.

The survival of the dopamine hypothesis

A forerunner of the dopamine hypothesis was the view of Deniker (1960) that the extrapyramidal effects of neuroleptic drugs are related to their therapeutic influence in schizophrenia. This view was widely doubted, principally because the two actions appeared dissociated in some drugs (e.g. thioridazine). With the discovery that dopamine is depleted in the striatum in Parkinson's disease (Ehringer & Hornykiewicz, 1960) and that some neuroleptics act on dopaminergic mechanisms (Carlsson & Lindqvist, 1963), the hypothesis became more explicit and testable in the form that neuroleptic drugs exert their therapeutic effects by interfering with dopaminergic transmission. With the development of the dopamine sensitive adenylate cyclase assay for dopamine antagonist activity, it was established that, for the range of phenothiazine and thioxanthene compounds, dopamine antagonist activity correlates well with therapeutic potency.

---

*Commentary arising from preceding paper by T. G. Dinan

However, two serious problems for the hypothesis emerged. First, the butyrophenone compounds were less effective in this assay than was predicted from their therapeutic effects. Secondly, discrepancies between dopamine antagonist activity in behavioural assays and therapeutic activity were apparent (Crow & Gillbe, 1974). For example, thioridazine appeared to be much less effective than chlorpromazine in an assay of dopamine antagonist activity (inhibition of amphetamine-induced turning behaviour in rats with nigrostriatal lesions), while the two drugs were approximately equipotent in reducing locomotor activity, an action which therefore seemed more closely related to their therapeutic effectiveness.

The first problem was resolved when the butyrophenone binding assay (for what is now described as the D2, or non-adenylate cyclase-linked receptor) was developed (Seeman *et al*, 1976). On this receptor the potency of the butyrophenone compounds relative to the phenothiazines and thiaxanthenes was shown to be comparable to their therapeutic effects.

The second problem was removed when it was demonstrated in the turning rat model that cholinergic antagonism reverses apparent dopaminergic blockade (Muller & Seeman, 1974). It appears that some neuroleptic drugs (e.g. thioridazine) also possess muscarinic cholinergic antagonist activity (Miller & Hiley, 1974). This accounts for their low incidence of extrapyramidal effects and low potency in the turning-rat model of DA activity.

The dopamine hypothesis thus was able to explain what previously appeared as discrepant observations. This increases one's confidence in its explanatory power.

A further stringent test of the hypothesis was made possible by the observation that DA antagonist activity of the thiaxanthene compounds is limited to the *cis*-stereoisomers (Miller *et al*, 1974). In a clinical trial in patients with acute episodes of illness we were able to show (Johnstone *et al*, 1978) that the *cis*-isomer of flupenthixol is significantly more active than the *trans*-isomer, which itself is no more active than placebo. For several pharmacological actions (e.g. noradrenergic, cholinergic and opiate antagonist activity) the two isomers do not differ. Therefore the antipsychotic effect presumably is unrelated to these receptors. The two isomers differ with respect to dopamine and serotonin antagonist activity. However, the serotonin antagonist potency of psychotropic drugs correlates poorly with antipsychotic efficacy. Therefore dopamine antagonism explains the stereospecificity of the antipsychotic effect and no ready alternative explanation is available.

Therefore one must ask concerning Dinan's hypothesis that actions on calcium-activated potassium conductance are relevant to the anti-psychotic effect: Is thioridazine approximately equivalent to chlorpromazine in this respect, and are both these drugs significantly more effective than promazine? Are the butyrophenones more potent than the phenothiazines and thiaxanthenes? Are the *cis*-isomers of the thiaxanthenes more potent than the *trans*-isomers? Unless the answers to each of these questions is yes, it seems that the Dinan hypothesis lags behind dopamine antagonism as an explanation of the antipsychotic effect.

Is there dopamine overactivity in schizophrenia?

Another origin of the dopamine hypothesis lies in the observation that the amphetamine psychosis closely resembles paranoid schizophrenia (Connell, 1958) and that the amphetamines exert their major behavioural effects by enhancing dopamine release in the brain (Randrup & Munkvad, 1966, 1967). Randrup & Munkvad (1965) were able to show that the behavioural changes induced in rodents by the amphetamines are selectively reversed (i.e. with a return of previously suppressed normal behaviours) by administration of neuroleptic drugs, but not by other sedative agents. These observations rather strongly suggest that it is the selectivity toward dopaminergic mechanisms which confers upon neuroleptics their particular properties; they also suggest the more ambitious formulation of the hypothesis that some form of dopaminergic overactivity underlies the positive symptoms of the disease (Randrup & Munkvad, 1972).

Compelling though these observations are, a caveat should be entered. Although everything seems consistent with the view that the amphetamines exert their psychotogenic effects via dopamine release, it remains puzzling why, if this is so, direct dopamine receptor agonists (e.g. apomorphine, bromocriptine) are not found to be psychotogenic in the same way.

The relative lack of psychotic potency of direct dopamine agonists remains something of an embarrassment for the dopamine theory of psychosis.

The theory would be greatly strengthened if it were possible to demonstrate an abnormality of dopaminergic transmission in patients. There is no compelling evidence of increased activity of dopamine neurones either from cerebrospinal fluid studies or from assessment of post-mortem brain samples for metabolites of dopamine (Crow *et al*, 1984). Investigations of the status of the D2 dopamine receptor, however, are at an interesting stage. Studies on post-mortem brain samples agree in finding an increase of approximately 80–100% in numbers of D2 receptors (Lee *et al*, 1978; Owen *et al*, 1978; Mackay *et al*, 1982; Cross *et al*, 1981), but the question of whether or not this change can be attributed to past neuroleptic medication is unresolved. There are now a number of techniques for studying the D2 receptor *in vivo*, and some of these have already been applied to patients whose drug-free status can be securely established. In one study with ^{77}Br-spiperone using single-photon emission tomography (Crawley *et al*, 1986), an increase ($P<0.05$) in striatum/cerebellum ratios of 11% by comparison with controls was observed in 12 patients who had been free of neuroleptics for at least 6 months. In a positron emission tomography (PET) study, a much larger increase (approximately 150%) was demonstrated in drug-free and drug-treated schizophrenics in maximum binding of ^{11}C-methylspiperone estimated by a method which involves administration of haloperidol between a first and second scan (Wong *et al*, 1986). Thus there are indications that D2 receptors may indeed be increased. However, there are problems with both techniques and it will be of particular interest to see whether the increase is confirmed by the PET technique using ^{11}C-raclopride (Farde *et al*, 1986). If it can be established that D2 receptor changes are associated with some component of the disease process, this will provide an explanation that will be difficult to resist of why it is that dopamine antagonist drugs ameliorate symptoms.

Is dopamine a plausible substrate for schizophrenic symptoms?

An element in Dinan's critique of the dopamine hypothesis is the suggestion that dopamine neurones are an unlikely location of the primary disturbance, because as a component of the basal ganglia they are not involved in higher cognitive activity. However, this argument ignores a number of considerations. First, the dopamine systems arising from the ventral mesencephalon project not only to the striatum but also to the nucleus accumbens (which has direct connections with hippocampus and other limbic structures) and the frontal cortex. In these sites, if not in the striatum, it may be supposed that dopamine release has an influence on higher cognitive processes.

Secondly, there is evidence that dopamine neurones, even in the striatum, have more than the simple motor function which is suggested by observations on Parkinson's disease. For example, Marshall *et al* (1974) and Ljungberg & Ungerstedt (1976) have drawn attention to the phenomenon of sensory inattention after unilateral nigrostriatal lesions.

Thirdly, there is a strong case that activation of dopamine neurones has rewarding as well as activating effects, as was first suggested on the basis of a study in which the rat mesencephalon was mapped for electrical self-stimulation responding (Crow, 1972).

These observations can be accommodated within the concept that dopamine neurones function as an 'incentive motivational' system which energises and directs the organism's responses toward significant environmental stimuli (Crow, 1973; Crow & Deakin, 1985). It is of interest that an early behavioural interpretation of the mechanism of action of neuroleptics is compatible with effects on such a system. On the basis of their experiments on chlorpromazine, Olds & Travis (1960) suggested that the drug "acts against a system which controls operant or 'voluntary' behaviour" and speculated that "counteraction of positive feedback processes subserving positive reinforcement mechanisms may be a key to the control of certain psychotic episodes".

Thus, in addition to the evidence from amphetamine psychosis that dopaminergic overactivity is correlated with psychosis, it seems that the functions of dopamine neurones are not inconsistent with their having a role in the pathogenesis of schizophrenic symptoms. One of the problems with Dinan's theory is that it appears to make no predictions about the selectivity of the effects of neuroleptics. Thus one might expect calcium activation of changes in potassium conductance to be characteristic of a wide range of neuronal elements (e.g. motor neurones and Purkinje cells as well as cortical neurones). Without further development it is difficult to see how the theory can account for the specificity of the antipsychotic effect.

An alternative to the dopamine hypothesis? – antiviral activity

Whether or not there is a disturbance of dopaminergic transmission in schizophrenia, the theory that neuroleptic drugs act by blocking dopamine receptors appears by far the best explanation we have of their effectiveness in treatment. Nevertheless, not least because their therapeutic effects are limited and no great advance in treatment is in prospect, we have to consider alternative possibilities.

One such alternative that intrigues me is that these drugs act by an antiviral mechanism. A number of recent authors (Torrey & Peterson, 1976; Crow, 1978; Hare, 1979) have thought that schizophrenia might be caused by a virus. I considered the possibility that the disease might be due to an exogenous pathogen (Crow, 1983) but dismissed this on the grounds that age of onset appears to be intrinsic to predisposition to the disease, i.e. it is not environmentally determined (Crow & Done, 1986). This consideration narrows down the type of viral agent that could be responsible to the class of agents that are either acquired *in utero* or integrated in the genome, i.e. transmitted as a gene (Crow, 1984). Included in the latter category are some types of retrovirus (Teich, 1982). In mice, integrated retroviruses are known to cause specific diseases, e.g. mammary tumours and leukemias. It is of considerable interest that actions of some neuroleptic drugs on diseases caused by retroviruses in mice have been demonstrated. For example, lytic actions of a variety of neuroleptic drugs on retroviruses *in vitro* have been reported (Wunderlich & Sydow, 1980), and suppression of disease manifestations caused by retroviruses has been reported in the case of mammary tumours by reserpine (Wunderlich & Zotter, 1982) and Rauscher leukemia virus by haloperidol (Wunderlich *et al*, 1980).

We recently investigated possible antiviral effects of a limited range of psychotropic drugs (including chlorpromazine and lithium) on herpes simplex virus infectivity and synthesis *in vitro* (Patou *et al*, 1986). Reductions in virus titre were observed with several compounds, including lithium. However, among the neuroleptics tested there was no relationship with antipsychotic efficacy; for example, promethazine had effects but trifluoperazine did not, and *trans*-flupenthixol was somewhat more effective than the *cis*-isomer. It remains possible that more specific effects would be observed on integrated pathogens, particularly those expressed in the central nervous system. This line of investigation seems worth pursuing.

If an antiviral mechanism of action is postulated, the question of what role dopamine plays must also be considered. One possibility is that the relation between antipsychotic potency and dopamine antagonism is no more than a coincidence. This cannot be excluded, but for the reasons given above it seems unlikely. Two other possibilities come to mind. The first is that changes in dopaminergic function are secondary to pathological changes elsewhere. There is increasing evidence for a focus of structural change in the temporal lobe (Brown *et al*, 1986; Bogerts *et al*, 1985). Czernansky *et al* (1983, 1985) have shown in animal experiments that an epileptic focus in the amygdala can cause changes in numbers of dopamine receptors in the striatum. Similarly Pycock *et al* (1980) describe how an increase in receptor numbers in the striatum follows lesions to the frontal dopaminergic projection. Along these lines one might propose that episodes of positive symptoms (assuming these to be dopamine related) are only an indirect consequence of the primary pathological change. In this case the effects of neuroleptics would be entirely symptomatic, a possibility which is not seriously challenged by the existing literature.

The second possibility is that there is some more direct relationship between the pathological agent and the dopamine receptor. For example, one might consider whether the agent gains access to particular cells by way of the dopamine receptor in the way that the human immunodeficiency virus gains access to lymphocytes via the T4 receptor. Alternatively, one could hypothesise that the virus is integrated in the genome at a site which is related to the transcriptional control of the receptor.

Both these possibilities concerning the role of dopamine deserve consideration on the grounds that they might open up new approaches and also perhaps explain the prophylactic efficacy of neuroleptics, which sits somewhat uneasily with the notion that these drugs act by a simple receptor blockade.

Concluding comments

The dopamine theory of the action of neuroleptic drugs remains the most plausible explanation of their therapeutic effects because

(a) it accounts well for the relative potency of the whole range of phenothiazine, butyrophenone and thiaxanthene drugs, including the stereoisomers of flupenthixol

(b) it is consistent with the fact that agents (e.g. amphetamines), acting by dopamine release, have psychotogenic effects, and that both the psychotomimetic effects in man and behavioural effects in animals are reversed by neuroleptic drugs.

Although it is as yet unclear whether there are disturbances of dopaminergic transmission in schizophrenia, an increase in receptor numbers remains a possibility and is supported by recent imaging studies. Moreover, the function of dopamine neurones in sensori-motor integration as revealed by animal experiments is not inconsistent with a disturbance of these systems contributing to psychosis. The two major outstanding difficulties for the dopamine hypothesis are the relative lack of psychotogenic effects of direct dopamine agonists, and the apparent weakness of simple dopamine antagonism as an explanation of the prophylactic efficacy of these compounds.

Notwithstanding its general success, the dopamine hypothesis does not seem to be generating further progress, particularly the introduction of more effective treatments. Therefore alternative hypotheses must be considered. One such hypothesis is that these drugs have actions on pathogens that are integrated in the genome but expressed to cause episodes of disease. While it is conceivable that such a mode of action might bear a relation to dopaminergic transmission (e.g. if the pathogen has an affinity to the D2 dopamine receptor), the hypothesis (like other current theories of the antipsychotic effect) lacks the explanatory power of the dopamine theory in that it has yet to be subjected to the experimental tests that the dopamine hypothesis has survived.

Is There More Dementia, Depression and Neurosis in New York?

A Comparative Study of the Elderly in New York and London Using the Computer Diagnosis AGECAT

J. R. M. COPELAND, B. J. GURLAND, M. E. DEWEY,
M. J. KELLEHER, A. M. R. SMITH and I. A. DAVIDSON

A computerised diagnosis, AGECAT, is applied to data from random community samples of the elderly in New York and London in order to examine the prevalence of mental illness in the two cities, especially the result reported from the same study, using a different diagnostic procedure, that the proportion of dementia was higher in New York. The greater proportion of dementia in New York is confirmed for all AGECAT's levels of diagnostic confidence, for both sexes and at all half-decades over 65 years. Provided that this difference is upheld and genetic differences can be discounted, these findings would seem to support a contributory environmental cause for dementia. Proportions of depression as a whole are similar in both cities. Syndrome case and sub-case levels of neurotic disorder are generally higher in London.

From a study of the elderly aged over 65 living in the communities of New York and London, the US–UK Cross-National (Diagnostic) Project reported the prevalence of dementia in New York to be significantly higher than that in London (Gurland *et al*, 1983). Because only the London sample had been interviewed and diagnosed entirely by psychiatrists, it had not been possible to compare psychiatric diagnosis between the two cities. An algorithm had therefore been devised by which subjects could be allotted by the interviewer to levels of illness described as 'pervasive' dementia and 'pervasive' depression. Here we re-examine the data by applying a recently developed computerised diagnosis, AGECAT.

Epidemiological studies in the past have suffered from poor method. Representative samples have always been difficult to draw, and early studies employed unstructured methods and intuitive diagnoses. More recently semi-structured interviews have been used and attempts have been made to standardise the diagnostic process. In 1986 Copeland *et al* reported the development of a computerised diagnostic system, AGECAT, which could be applied to data derived from the Geriatric Mental State (GMS) and the CARE interview. In the study described here, both a semi-structured interview and a computer diagnostic system are used to provide a reliable 'yardstick' for comparison between two community samples.

Method

What is being measured?

It is important that a case be defined for the purpose for which it is to be used (Copeland, 1981*a*). However, there are stages in the definition of a case which we have attempted to define elsewhere (Copeland *et al*, 1986). At the point where symptoms group to form a pattern recognised by a psychiatrist as an illness, we identify a 'syndrome' case. Such a case is a profile of symptoms only. If this is the only syndrome present, or if several syndromes reach case level in the same individual and the primary one is selected, the subject becomes a diagnostic case of that syndrome. For the London/New York community study further criteria were introduced: that the severity of the condition merited professional intervention, and that the subject's age be restricted to 65 years and over. As these further criteria were added to that of the pure syndrome we have called these 'criteria cases for intervention'.

The History and Aetiology Schedule (HAS) for an informant, which deals with historical facts, was not developed in time for this community study. Therefore, the AGECAT system as used here is only able to identify cases at the *syndrome* and *diagnostic syndrome* level. In consequence there may be some 'over-diagnosis' of cases which, although fulfilling the criteria for syndrome cases, would not have merited intervention in the judgement of the psychiatrists; for example, states of bereavement, and longstanding and distressing fluctuations of mood, which share a cross-sectional mental-state picture of depression. Nevertheless, we have now shown a satisfactory concordance between AGECAT and psychiatrists' diagnoses in a number of studies (Copeland *et al*, 1986, 1987).

Interview method

In 1976 the development of the GMS, a semi-structured mental-state interview for the elderly, was reported (Copeland *et al*, 1976, Gurland *et al*, 1976). For the community a much shortened version was prepared, omitting many of the psychotic sections, to which was added a large number of social and general medical items, to form the CARE interview. The CARE interviews have since been modified and different forms are now available.

AGECAT

The AGECAT system was developed on a theoretical model based on clinical experience (Copeland *et al*, 1986). It was then tested against samples of patients, readjusted and retested. It brings together items from the GMS and those schedules derived from it into 157 symptom components, which are then formed into eight diagnostic 'clusters', each consisting of a number of groups representing symptoms important for diagnosis. Scores on these groups determine the level of diagnostic confidence for each subject on each diagnostic cluster. The diagnostic clusters are organic, schizophrenic, manic, depressive (psychotic and neurotic), hypochondriacal, obsessional, phobic and anxious.

In stage 2 the levels are compared across clusters, following the above hierarchy, so that levels towards the beginning tends to dominate those towards the end. A principal diagnosis emerges, an alternative diagnosis if appropriate, and for each diagnostic cluster, the corresponding levels of diagnostic confidence or certainty (Dewey & Copeland, 1986). In addition, a decision is made on whether or not the symptoms rank as a syndrome case. For all clusters, levels of confidence 3, 4 and 5 represent syndrome case levels, and 1 and 2 sub-case levels. Symptom profiles can be derived, and organic and depression scores suitable for case-finding can be quickly calculated.

In the full diagnostic system the results of stage 2 are processed with data from the HAS (stage 3) and the diagnostic syndromes are broken down into individual diagnoses. This stage was not available for this analysis.

Interview personnel

All subjects in the London sample were interviewed by research psychiatrists of senior registrar status or above, employed full-time by the project. In New York only half the sample was seen in this way; the rest were interviewed by social scientists who were trained in the method and whose reliability had been satisfactorily assessed against psychiatrists' ratings. Reliability studies were performed between interviewers and between teams and found to be satisfactory. Teams exchanged members so that all principal interviewers interviewed in both cities.

Sample

In London the study area chosen was Greater London. A random sample was taken of 3000 general practitioners serving Greater London. Permission was obtained from each chosen general practitioner, and his patients aged over 65 were random-sampled at the local Family Practitioner Committee's premises. Only one practitioner refused to co-operate with the study and his patients were 'lost'.

In New York a state sample was obtained from the New York State Office for Ageing. In all 1726 households were chosen in metropolitan New York, obtained in 66 dwelling clusters throughout the five boroughs. A series of random sub-samples was drawn in each city, and a comparison of the consistency of the sub-samples provided a check on how well they represented the whole. Each dwelling unit was visited up to four times; if no respondent was found, information was sought from neighbours where possible. The interview response rates were 81% in London and 71% in New York. In all, 396 interviews were completed in London and 445 in New York.

Results

Demography

Table I shows the age distribution of the sample. The mean age was 74 in both cities, and the distribution by half-decades was similar, except that the proportion of males aged 80–89 in the London sample was less than half that in New York. This group would have been aged 18–30 at the time of the outbreak of the First World War. At over 90 years the number of males was very small but the proportions were similar in both cities. The rest of the demographic findings, which have been described in detail by Gurland *et al* (1983), will only be summarised here. In the New York sample 10% were black, 39% Catholic and 35% Jewish, compared with 1%, 10% and 3% respectively in London. In the New York sample 60% had been immigrants, compared with only 10% in London. The distribution on occupational status was much the same in the two cities, with a small preponderance of unskilled workers in London. Marital status showed no significant differences. A census of New York City and one of London, both taken in 1976, showed a close approximation for sex and age with the corresponding city sample described here (New York State, 1976; HMSO, 1976).

TABLE I
Distribution of the samples by age and sex

	New York (n=445)		*London (n=396)*	
Age	*Males (%)*	*Females (%)*	*Males (%)*	*Females (%)*
65–69	43	57	38	62
70–74	39	61	35	65
74–79	37	63	42	58
80–84	43	57	21	79
85–89	39	61	17	83
90+	18	82	17	83

Diagnostic comparison

A greater frequency of depression had been expected in New York because the high crime rate, the problems of health care, shortage of public housing, and less centrally organised welfare were likely to result in more unpleasant life events among the elderly in that city than in London. Whereas, apart from the possibility of a wider racial and genetic mix, there seemed little reason to assume that the level of dementia would vary between the two cities.

The findings did not fulfil these expectations. Table II shows the distribution of AGECAT diagnostic cases by sex. AGECAT finds almost twice as much organic disorder in the New York sample as in the London sample for both sexes ($P<0.02$), whereas the levels for depression and the neuroses are not significantly different. Table III sets the AGECAT diagnostic cases beside 'pervasive illness', psychiatrists', and the DSM-III (American Psychiatric Association, 1980) diagnoses made 'blind' by a psychiatrist (JRMC) reviewing the AGECAT symptom components. In the original study, Gurland *et al* (1983) defined 'pervasive' and 'limited' dementia and depression (the 'hand-applied' algorithm they provide has no relationship to the AGECAT method, which at this stage does not take social factors into consideration), and reported a point (past month) prevalence rate for 'pervasive depression' of 13% in New York and 12.4% in London, whereas the rates for 'pervasive dementia' were 4.9% in New York and 2.3% in London. Rates for 'limited dementia' were also higher in the New York sample.

TABLE II

Comparison of the samples by sex using AGECAT diagnostic cases (New York n=445, London n=396)

	Males		*Females*	
	New York (%)	*London (%)*	*New York (%)*	*London (%)*
Depression	13.0	13.1	18.3	22.8
Mania	0.0	0.0	0.4	0.0
Organic illness	5.7	2.2	10.1	5.4
Neuroses	1.7	1.5	1.1	2.3
Total ill	20.4	16.8	29.9	30.5

Table III also shows the comparison between New York and London for types of depressive illness. AGECAT at this stage splits the depressive category into neurosis (mental state similar to 'reactive') and psychosis (mental state similar to 'endogenous'), which is here a qualitative distinction. DSM-III uses a mixed method, partly qualitative in the distinction between major affective disorders and dysthymic disorders, and partly aetiological in the removal of bereavement from the depressive rubric. AGECAT separates bereavement and other depressive states of supposed separate aetiology on the basis of HAS data, not available in this study. DSM-III diagnoses are only available for the London sample. There is similarity in the proportions of AGECAT depressive psychosis (3.3%) and DSM-III 'major affective disorder' (4.6%). The proportion of 12.4 for 'pervasive depression' is similar to that for all types of DSM-III 'depression' taken together. Case levels for AGECAT depressive neurosis and DSM-III dysthymic disorder are bound to cause difficulties, as such conditions presumably lie on a continuum with normality.

As expected, AGECAT, identifying at the syndrome case level, selects the largest number of cases, but nevertheless agrees closely with the London interviewing psychiatrists. The proportions for 'pervasive' and DSM-III illness also agree closely; both methods are more restrictive than AGECAT and the psychiatrists.

Organic diagnosis

Table IV shows the distribution of AGECAT diagnostic organic states by levels of confidence. As explained above,

TABLE III

Comparison of the samples using AGECAT, pervasive illness, psychiatrists' and DSM-III diagnoses where available

	New York (n=445)		*London (n=396)*

TABLE IV
Distribution of AGECAT diagnostic organic syndromes (sub-case and case) by levels of confidence of diagnosis; numbers New York 63 (14.2%), London 25 (6.3%)

	Sub-case		*Case*		
	O1	*O2*	*O3*	*O4*	*O5*
New York: % of full sample ($n=445$)	0.5	5.4	4.1	4.3	0.0
London: % of full sample ($n=396$)	0.3	1.8	2.8	1.5	0.0

it is possible for a subject to achieve confidence levels of 3 and above (case levels) on more than one diagnostic cluster. For example, a subject may achieve both organic and depression syndrome case levels, but emerge finally as a diagnostic case of depression. Psychiatrists might call such a case 'pseudo-dementia', where the organic syndrome would be regarded as secondary to the depression. Such secondary organic syndromes are not included in this table. 'Diagnoses' also refers not only to cases (levels O3 to O5), but also to sub-case levels (O1 and O2). Table IV shows that a preponderance of organic 'diagnoses' in New York is not confined to case levels 3 and above. Such preponderence is evident at all levels of confidence except 5.

There are two principal types of diagreement between AGECAT and psychiatrists' diagnoses. One is the disagreement on category; that is, AGECAT designating a case as organic but the psychiatrists diagnosing it as depression. The other is where AGECAT agrees with the psychiatrists on the diagnosis, such as an organic syndrome, but disagrees on whether or not the subject is a case. Clearly, psychiatrists can vary in their concept of case levels and therefore, in simple case/non-case decisions, prevalence figures can differ widely. One of the merits of AGECAT lies in its consistency both in choosing diagnostic categories and in choosing case and sub-case levels. Sub-case levels of 2 would probably contain subjects whom some psychiatrists would recognise as cases and others not. Similarly, some AGECAT cases at level 3 might not be recognised by some psychiatrists. In practice, AGECAT appears to agree with most psychiatrists on its selection of cases, but allows investigators to record the proportions of subjects at each confidence level and thus to determine which choice of levels best suits their study. Studies are now being undertaken to determine the outcome of AGECAT sub-case levels 1 and 2, and whether or not future cases can be identified among them.

Figure 1 shows the distribution of AGECAT diagnostic syndrome cases of organic disorder by age in half-decades for the two cities. There is a greater or lesser preponderence of organic cases in New York at all six age periods. AGECAT cases are shown as a percentage of the sample at that age for each city. Proportions of community-dwelling subjects aged 80 or more suffering from dementia were 21.2% in New York and 15.7% in London. After age 85 numbers were comparatively small even for these samples, so that less reliance can be placed on the accuracy of findings at these age periods. The increasing proportions of dementia with age are statistically significant in the two cities (London $P<0.05$, New York $P<0.02$).

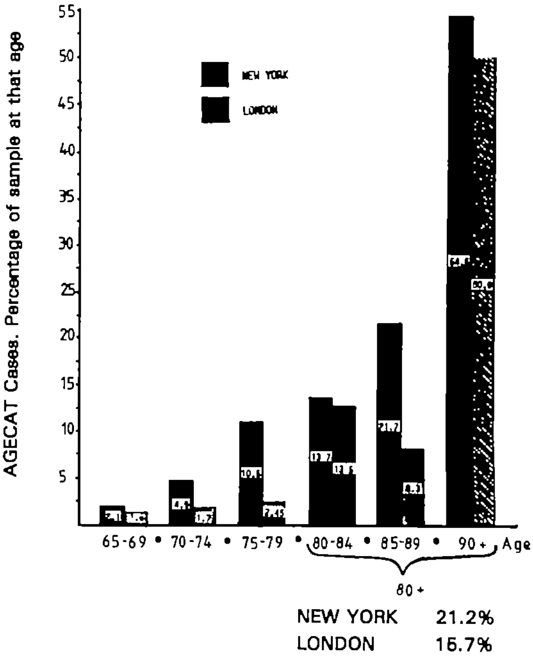

FIG. 1 Distribution of AGECAT diagnostic organic syndrome cases by age.

Depressive diagnosis

Where the distinction between case and non-case is drawn usually rests on the arbitrary judgement of the psychiatrist. AGECAT tries to simplify this problem by distributing subjects on case and sub-case levels (Table V). Here there is comparatively little overall difference between the proportions of these cases for the depressive confidence levels, across both cities. The tendency for there to be more depressive psychosis in London than in New York is seen to be mainly at the higher level (DP4) (not significant).

Figure 2 shows the distribution of diagnostic syndrome cases of depression by age. Like the previous figure for organic diagnostic syndromes, it excludes sub-case levels (D1 and D2). Taken overall, differences between the two cities are not striking and there is no consistent preponderance of depression cases in any one city. Again, findings for those aged over 85 are less certain because of small numbers than for the other age groups. For subjects aged 80 years and over the proportion of AGECAT diagnostic syndrome cases of depression is similar in both cities: New York 15.3%, London 14.3%.

Neurotic diagnosis

Table VI shows AGECAT diagnostic syndrome cases and sub-cases of neurotic disorders in the New York and London samples. If the symptoms of neurotic illness also lie on a continuum with normal behaviour, so that the differences between cases and non-cases are primarily quantitative, it will be difficult to draw the distinction. AGECAT finds remarkably few cases of pure neurosis in the total sample of 841 subjects in both cities. However, the interviewing psychiatrists themselves found only 4.1% of neuroses in London. Table VI shows that where the level for case identification is drawn will make a considerable difference in prevalence rates, at least for anxiety and obsessional neurosis. Case and sub-case levels of obsessional neurosis taken together are strikingly more common in London than in New York ($P<0.001$).

Figure 3 shows the distribution of AGECAT diagnostic syndrome cases and sub-cases of neurotic disorders by age for the two cities. The proportions of cases of neurosis are so small that they are shown here added to the sub-cases. If the division between cases and sub-cases is quantitative, the distribution of cases would be expected to follow that of sub-cases, although in Fig. 3 the proportion of cases to sub-cases is not constant between the age groups. The

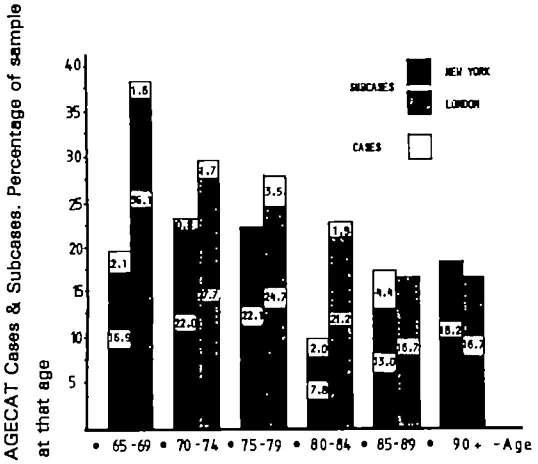

FIG. 3 Distribution of AGECAT diagnostic neurotic syndrome cases and sub-cases (levels 1 and 2) by age.

consistent tendency for there to be a higher proportion of sub-cases in London than in New York is demonstrated ($P<0.001$), although this is not necessarily reflected in case levels. There is also a tendency (not significant), at least in London, for sub-case levels to decline with age, which is not mirrored by the proportions of cases until after age 85, when findings are less certain because of smaller sample numbers.

The GMS symptom components were compared to reveal those significantly more common in one city than the other, even when allowance was made for the large number examined. Consistent with the other findings, the symptoms more common in London ($P<0.05$) reflect neurotic problems ('free-floating anxiety', 'tension', 'loss of interest', 'irritability', 'persistent thoughts') and other obsessional symptoms ('checks, washes repeatedly, excessively and cannot resist'), while those in New York were organic in type, concerning memory performance ('interviewer's name wrong on the first and second occasion', 'disorientation in place' and 'gives incorrect or incomplete address') ($P<0.05$).

Discussion

Levels of organic illness

The higher proportions of organic illness in New York are confirmed by AGECAT comparisons. These higher proportions are evident at all case and sub-case levels, for both sexes and across all age groups (half-decades) 65 and over. We have discussed possible explanations for this surprise finding elsewhere (Gurland *et al*, 1983; Copeland & Gurland, 1985). In short, a number of possibilities have been examined and rejected. When all five random sub-samples in each city were examined, the mean 'rational score' for dementia (Gurland *et al*, 1983) was higher in each New York sub-sample than for any London sub-sample except one, where the proportions were the same. A one-year follow-up study conducted in both cities (response rate in New York 72%, in London 63%) showed that the ratio for the diagnoses of dementia, assessed as 'pervasive dementia', between New York and London remained the same in both direction and magnitude, even when response rate at follow-up varied between sub-samples. Follow-up also tended to confirm the initial diagnosis. All nine cases in London diagnosed by the psychiatrists as dementia and followed up (the interviewer had no knowledge of the initial diagnosis) were confirmed as dementia one year later by the research psychiatrists. One-third of all those cases diagnosed as dementia in New York had died by the time of the one-year follow-up, compared with none in London, thus making it unlikely that the higher prevalence in New York resulted from longer length of illness, or earlier death in London. Examination using latent class analysis to classify dementia showed that the proportion of new cases arising in the sample during the year of the follow-up was higher in New York (2.4%) than in London (0.4%). A similar proportion of demented subjects was found to have entered institutions during the one-year follow-up in both cities (New York 9.5%, London 11.1%). When the populations were adjusted for age, sex, race and country of origin, non-white and foreign-born, the diagnostic proportions were unchanged.

There was some correlation between depression and dementia in New York. AGECAT is helpful here as it records separately each syndrome confidence level. The first possibility is that organic cases were under-represented in London because that proportion associated with depressive symptoms was incorrectly diagnosed as depression. However, there are no depressed cases in the London samples which are also syndrome organic cases. There are five associated with level O2. Three of these were followed up at one year. One had, indeed, become a case of dementia, moving to level O3 while the depressive levels had weakened, but of the other two, one was fully recovered and the other had become a pure case of depression. There would, therefore, seem little evidence to support this view.

The alternative possibility is that organic cases in New York were over-represented because depressive pseudo-dementias were misdiagnosed as organic. There are five organic cases associated with syndrome levels of depression, all but one of neurotic depression. Unfortunately, follow-up data are not available for these subjects, but if all five were assumed to be misdiagnosed it would still leave 32 organic cases in New York to 17 in London.

The possibility that the higher proportion of organic cases in New York was due to higher proportions of multi-infarct dementia seems unlikely, as the proportion of subjects with either history or evidence of a stroke was identical in both cities. The possibility that hospitals, nursing homes or social service accommodation might admit higher proportions of dementing clients in London also seemed unlikely, partly because of the very small proportion of the elderly population in such facilities, and because a subsequent study comparing psychiatric diagnoses in a random sample of New York and London hospitals, nursing and other homes (Gurland *et al*, 1979) showed the proportions of organic illness to be higher in New York institutions.

The finding of more dementing illness in New York among the elderly requires replication. So far we can advance no adequate explanation for it, although tentative suggestions have ranged from the high consumption of contaminated alcohol during the years of prohibition to possible dietary deficiency among the high immigrant New York population. We found no relationship between race and dementia in the general analysis. If genetic factors can be excluded and the difference upheld, these findings would seem to go some way towards supporting a contributory environmental cause for dementia.

Levels of depressive illness

It is also of interest that the expectation of more depression and neurotic illness in New York was not borne out. Depression seems no more common in the elderly than in the young. The psychiatrists' figure of 17% in London mirrors the 16% found by the same project in an earlier study in the old London borough of Camberwell, in collaboration with Brown & Harris (1978), using the Present State Examination in a population of younger women (aged 19–65). However, this overall figure for those aged 65 and more conceals higher proportions for both sexes before age 70, followed by a gradual decline for women to the tenth decade. The initial fall for men occurs between 65 and 74, with a steady increase in depression from then onwards. However, once again, findings are less certain in these upper age groups where numbers in the sample are small. It should be noted that although levels of crime against individuals were shown to be higher in New York than in London, complaints of fear of crime and of general neighbourhood deterioration were similar in both cities. Actual differences did not, therefore, seem to reflect their perception. Levels of physical illness, disability and dependence were similar in both cities. We have suggested (Copeland, 1981*b*) that unpleasant life events which have a causal role in depression may have to be perceived not only as painful and unpleasant but also as inevitable and unchangeable, representing for the subject an unpleasant stress before which he or she feels helpless. It seemed likely that the elderly of this generation, although they perceived many life events as unchangeable, did not necessarily perceive them as painful or unpleasant. To be perceived as painful, social events or conditions may have to fall short of expectations. Although living appeared to the interviewers to be much more difficult and stressful in New York, and this was amply borne out by the evidence, it probably did not fall short of expectation, especially for this largely immigrant population. Certainly there were instances in London when the interviewees expressed gratitude for their social conditions, recollecting how their parents had suffered at their age, even though to the interviewers, social standards were unsatisfactorily low.

We have already recorded (Gurland *et al*, 1983) that only 3% of those with 'pervasive depression' in New York and 14% in London were receiving anti-depressant medication. Just as disturbing was the high proportion of benzodiazapines prescribed, often in the opinion of the interviewers inappropriately, without concurrent anti-depressant therapy (31% of depressed subjects in New York and 18% in London). In New York, 93% of the depressed and 81% of the total sample had seen a doctor in the previous year before interview, and 82% and 74% in London.

Levels of neurotic illness

The low proportions of neurosis in the two cities, both on psychiatrists' diagnosis in London and on all AGECAT levels, was a surprise finding. If the level for anxiety neurosis is lowered to between AGECAT levels 1 and 2 rather than between levels 2 and 3, the proportion rises to over 16% in both cities. Nevertheless, there are very few subjects with moderate or severe anxiety which is not also associated with other mental illness. The preponderance of obsessional symptoms in London, particularly at the sub-case level, is presumably a cultural difference in the subjects. If, as is sometimes suggested, obsessional symptoms reflect states of insecurity, then we might have expected greater insecurity among the immigrant population of New York. It may be argued that AGECAT case levels for neurosis are pitched too high, but in replication samples, the proportions of neurotic cases identified by AGECAT have been similar to those identified by the psychiatrists. As pointed out earlier, psychiatrists are not skilled in distinguishing between cases and non-cases. A much earlier study (Copeland *et al*, 1975) showed that psychiatrists tended to rate lower levels of psychiatric pathology than general practitioners when viewing the same video-tapes of psychiatric patients. It was suggested at that time that psychiatrists would tend to rate examples of mental illness 'down' in relation to their experience of more severe illness, while those without such experience would tend to rate symptoms 'up', against their concept of normal behaviour. Such rating practices might lead psychiatrists to identify fewer cases of neurosis than general practitioners. A study comparing AGECAT diagnoses of neurotic disorders against general practitioner diagnoses could provide further information on the way mental illness in the elderly is perceived by different groups of doctors. Nevertheless, apart from anxiety and depressive neurosis, and, possibly in London, obsessional neurosis, other forms of neurotic illness appear to be rare in the elderly at any level of diagnostic confidence.

We have attempted to demonstrate the use of the AGECAT computerised diagnostic system for comparing mental illness in two samples of elderly subjects. We believe it is helpful to have a standardised method of diagnosis which can be applied reliably and consistently to different populations, which allows quantification of the levels of confidence in diagnosis, and especially identifies and grades sub-case levels.

Acknowledgements

The authors would like to acknowledge the contribution of the members of the teams of the US-UK Diagnostic Project, especially L. Sharpe, R. Simon, J. Kuriansky, L. Dean, P. Stiller, R. Bennett, D. Wilder, J. Teresi, R. Golden, D. Cook, M. L. Robinson, R. Parker, A. Mann, Y. Tsegos, and B. Robinson. They would also wish to thank the project consultants J. Zubin, the late A. Goldfarb, W. E. Deming, J. Fleiss, M. Kramer and F. Post. The study was funded mainly by grants from the National Institute of Mental Health, and by the Administration on Aging, the New York State Office of Mental Health and the Department of Health and Social Security, London.

Detention of 'Psychopathic Disorder' Patients in Special Hospitals

Critical Issues

A. T. GROUNDS

The detention of offenders in the legal category 'psychopathic disorder' in special hospitals for treatment raises a number of critical issues. There are doubts about the nature of the disorder; what constitutes treatment; who is 'treatable'; the effectiveness of treatment; and whether evidence of psychological change implies reduced risk of reoffending. In view of these uncertainties, it is argued that indeterminate hospital orders may provide an unrealistic and unjust legal framework for treating 'psychopaths' in special hospitals, and the use of powers under the Mental Health Act to transfer such patients to hospital during the course of prison sentences is a more appropriate alternative. This provision could be used more frequently, subject to improved safeguards of the right of release at the expiry of sentence.

In general penal policy during recent decades there has been a growing disillusion with rehabilitation and treatment as objectives of sentencing, firstly because of doubts about their effectiveness (Martinson, 1974; Brody, 1976), and secondly because they are held to be unjust (Lewis, C. S., 1953; von Hirsch, 1976; Bowden, 1985). Nevertheless, a small number (under 30 a year) of offenders in the Mental Health Act category 'psychopathic disorder' continue to be sentenced by restricted hospital orders and admitted to special hospitals. They represent a tiny minority – less than 1 in 2000 – of those sentenced in the criminal courts for violent and sexual offences. A current approach to the assessment and treatment of 'psychopaths' in one of the special hospitals has been described by Grounds *et al* (1987). Medical recommendations for their admission under restricted hospital orders may rest on an implicit belief that indeterminate sentencing for psychiatric treatment is appropriate for such individuals, and that treatment can reduce the risk of reoffending. When this view is set against the current climate of opinion in criminology and penal policy it looks anachronistic: it maintains the optimistic spirit of the East & Hubert (1939) report in its assumption that psychotherapy may be effective in reducing the risk of future antisocial behaviour in selected cases.

This paper will consider six critical questions concerning the detention of 'psychopathic' offenders in hospital for treatment: Do such offenders have a definite mental disorder? What constitutes treatment? Who is 'treatable'? Is treatment effective? Does psychological change imply reduced risk of reoffending? Is indeterminate sentencing for treatment a fair exchange for sentencing based on principles of criminal justice?

The category of 'psychopathic disorder'

The legal term 'psychopathic disorder' in the 1983 Mental Health Act is defined as "a persistent disorder or disability of mind (whether or not including significant impairment of intelligence) which results in abnormally aggressive or seriously irresponsible conduct on the part of the person concerned". The troubled historical origins of the legal definition and of the underlying clinical concepts – "semantic variations on a dubious theme" – are documented by Walker & McCabe (1973) and Lewis (1974). Walker & McCabe's (1973) examination of how the legal term is used led them to conclude that as a 'diagnosis' 'psychopathic disorder' had no explanatory, descriptive, prognostic or therapeutic function. In practice it is used as a pseudo-diagnosis; a label attached to offenders with a variety of abnormalities to help the psychiatrist "get his patient through the customs-barrier of the courts if he wants to." The Butler committee (Home Office, 1975) also concluded that: "The class of persons to whom the term 'psychopathic disorder' relates is not a single category identifiable by any medical, biological or psychological criteria"; and studies of 'psychopathic disorder' patients in special hospitals (Blackburn, 1982) confirm the variety of clinical features subsumed under this term. The category of 'psychopathic disorder' "remains ill-defined, circular and does not embrace a homogeneous group of individuals" (Blackburn, 1983).

It is therefore a shaky legal foundation on which to select some offenders for diversion from the penal system into indeterminate hospital care.

What constitutes treatment?

There is little consensus about what constitutes treatment for 'psychopaths'. The interpretation of the term 'medical treatment' in the Mental Health Act is general: "'medical treatment' includes nursing, and also includes care, habilitation and rehabilitation under medical supervision". Traditionally in special hospitals the equally non-specific term 'milieu therapy' has been described as treatment (McGrath, 1966; Royal College of Psychiatrists, 1983); but as Gunn (1978) has pointed out: "it is difficult to argue that in hospitals of any kind a structured disciplined environment is a *medical* strategy; it is simply a prerequisite for making sure that patients stay where they are told to stay." McGrath (1968) also questioned to what extent "a benevolent custodial and expectant regime" could be justified as 'treatment'.

If treatment is defined in more specific terms, what counts as adequate treatment for 'psychopaths' will vary in different contexts. In an out-patient setting it may be justifiable to regard measures such as crisis intervention, and long term support without expectation of substantial personality change, as appropriate psychiatric treatment; but in a hospital setting where 'psychopaths' are detained for an indefinite period in maximum security this is not sufficient. Treatment is expected to produce personality change: the Home Office seeks evidence of this before agreeing to release, and for the offender too this is the promise implied by a hospital order. The therapeutic aims therefore have to be higher; and if they cannot be achieved the patient is being deceived.

'Treatability'

In the 1959 Mental Health Act, the term 'psychopathic disorder' included the clause that the disorder "requires or is susceptible to medical treatment." In the 1983 Mental Health Act the 'treatability' clause was changed and made a condition that had to be met for a long term treatment order to be made. For this purpose it must be held that medical treatment for the patient "is likely to alleviate or prevent a deterioration of his condition".

Medical recommendations for hospital orders under the 1959 Act included a section filled in by the reporting doctors, headed "Information to establish that the disorder or disability of mind requires or is susceptible to medical treatment". The specific items cited in the preadmission medical reports of the 'psychopathic disorder' patients ($n = 13$) in one ward in Broadmoor Hospital on 1 March 1986 were examined, and two main features were evident: first the wide variety of items mentioned, and secondly their lack of specificity. Some reports merely asserted that treatment was required, without reasons being given. Factors most frequently cited as evidence that the patient's disorder was susceptible to treatment were, first, the patient's self-concern or wish to have treatment; and secondly, being of a young age.

Even the fullest reports were expressed in general terms. For example: "He is a young man of good intelligence who is potentially capable of benefiting from psychotherapy and other forms of psychological treatment. He is anxious to have treatment". Others were more half-hearted: "In view of his young age it is worth trying treatment and the consultant at Broadmoor Hospital is prepared to undertake his treatment". The contents of the reports suggest there was little agreement about specific factors that indicate a likelihood of benefit from treatment, and they do not indicate what specifically distinguished this tiny group of serious offenders from others.

Lewis (1974) noted that the most obvious criticism of the legal definition of 'psychopathic disorder' centered on the 'treatability' clause. "The opinion of psychiatrists or other competent experts as to who requires or is susceptible to treatment will inevitably tend to be subjective and inconsistent." In an earlier paper, when discussing the role of medical diagnosis in a social context, he argued that, "Unless the criteria of ill health are independent and clear it is difficult or unsafe to use data based on them for purposes of selection" (Lewis, A., 1953). The force of this conclusion was ignored by the Butler committee (Home Office, 1975) and others since (e.g. Ashworth & Gostin, 1984) who, having recognised the uncertainty about what constitutes 'treatability', have nevertheless proceeded to argue that the legal criterion should be tightened up even further, so that doctors would be required to make more specific judgements and predictions about this issue. The proposal is self-contradictory and impracticable.

These difficulties are unlikely to be fundamentally altered by the use of the new Interim Hospital Orders (S.38, Mental Health Act 1983), but it is arguable that they may be useful in enabling prospective patients and hospital staff to make more realistic and informed assessments of whether a treatment alliance is possible than could be done prior to the 1983 Act.

Effectiveness of treatment

The general conclusions drawn from surveys of psychotherapy outcome research (Bergin & Lambert, 1978; Prioleau *et al*, 1983) and research on the effectiveness of corrective and rehabilitation programmes for offenders (Martinson, 1974; Brody, 1976) are gloomy. The available follow-up studies of special hospital patients do not enable us to relate outcome to specific treatment received (Black, 1984); however, such studies do indicate that patients in the category of 'psychopathic disorder' have a poorer outcome in terms of reconvictions than the mentally ill, and a history of prior criminal convictions is the factor most strongly associated with reconviction after release from special hospitals (Bowden, 1981; Black, 1982; Tennent & Way, 1984). These results suggest that, as is the case for offenders in the penal system, it is the pre-admission criminal profile that is the best predictor of reoffending; and it seems unlikely that the effect of hospital treatment is in general sufficient to offset its influence. Thus there is little empirical basis for confidence that, in detaining 'psychopaths' for treatment in special hospitals with the aim of reducing likelihood of reoffending, there is evidence to back up our therapeutic hopes and aspirations.

Does psychological change imply reduced risk?

The next issue is related. If, following treatment, some 'psychopaths' do show evidence of psychological and personality change, does such change imply that the patient's risk of reoffending is reduced? Medical recommendations to the Home Office or to mental health review tribunals for discharge or transfer have to be framed as if such an inference was valid, but there is currently a lack of any detailed empirical study confirming whether this is the case. The evidence from follow-up studies so far is not encouraging. If pre-admission variables such as previous convictions are the best predictors of reoffending, as is case for offenders in penal settings, there has to be doubt about the validity of inferring reduced likelihood of dangerous behaviour from evidence of personality or behavioural change in hospital.

Treatment instead of justice – a fair exchange?

The doubts surrounding the above issues lead to the last question. Is the admission of a 'psychopathic' offender to hospital on an indeterminate treatment order a fair exchange for a sentence determined by the sentencing court on criminal justice principles? The effect of psychiatric involvement leading to a hospital order is to remove the offender's right to have the length of time he spends in custody determined by the court on the principle of proportionality. Apart from the possibility of discharge by mental health review tribunals, discretion over the release of restricted patients lies with the executive, in the form of the Home Secretary, rather than the courts. Furthermore, tribunals have to base their decisions on clinical criteria, and cannot take tariff considerations into account. In general sentencing policy there is a weight of legal opinion opposed to the principle of indeterminate sentencing with release dependent upon the progress of the offender. Scarman (1978), for example, has argued that the determination of how long an offender remains in custody should be a matter for the sentencing court rather than the executive, in the absence of evidence that rehabilitation as a penal policy is effective. The balance of justice between the offender and the public "is best struck in open court". The indeterminate hospital order, under which continued detention depends on clinical criteria, operates on quite different principles. But in the case of 'psychopaths', where are the specific clinical features that justify treating this tiny group of offenders differently from the many thousands of others passing through the criminal justice system each year? The question can be answered more easily in the case of the mentally ill and handicapped than in the case of the 'psychopath'.

The admission of 'psychopaths' on indeterminate treatment orders cannot be validly justified on the sole basis that special hospitals provide more humane environments of care than prisons, or that hospital-based research offers the prospect of major breakthroughs in understanding and treatment. The reality of indefinite detention in conditions of maximum security is not so benign. Critics such as Goffman (1961), describing the destructive social dynamics of psychiatric institutions; Kittrie (1971), with his legal critique of "therapeutic tyranny"; and earlier still C. S. Lewis (1953), in his dramatic argument against the "humanitarian theory of punishment", all perhaps overstated their cases, but they have left a legacy of insights that are too incisive and unsettling to be easily dismissed.

These considerations should not be taken to imply that psychiatric help should not be offered to personality-disordered offenders. Patients in the legal category 'psychopathic disorder' have psychopathology from which they suffer (Craft, 1966; Blackburn, 1975, 1982); further descriptive research is required (Lewis, 1974); and psychiatric care and treatment should continue to be offered (Gunn, 1978). The question is, in the light of current knowledge about treatment and its effectiveness, what is the most realistic and just legal framework within which to carry out these tasks? It would seem preferable to find a way of ensuring that those who require care and treatment receive it but without forfeiting their rights to sentencing according to normal criminal justice considerations. The medical and penal issues need to be separated. This would also protect doctors from having unrealistic roles placed upon them as "medical underwriters of preventive detention" (Chiswick, 1982), with the attendant responsibilities of making judgements about future dangerousness and duration of custody: responsibilities which involve carrying the mantle of the sentencing court. Gunn (1978) has argued that compulsory indeterminate treatment for 'psychopaths' in special hospitals is "not entirely ideal because the same person has to act as custodian and physician in an area where there is doubt as to whether a medical disorder is present and where the criteria for custody may be quite different from the criteria for psychiatric treatment and response". Dell & Robertson (1986) reached similar conclusions in their comparative study of treatment and discharge decisions about mentally ill and 'psychopathic disorder' patients in Broadmoor Hospital.

Transfer to hospital during sentence

One way of enabling psychiatric treatment within the framework of normal sentencing is available under the Mental Health Act provision to transfer prisoners to hospital for treatment during sentence (S.47 of 1983 Act). This allows a proper separation of psychiatric and criminal justice considerations in dealing with such offenders, and Mawson (1983) has argued that it is a preferable option. Until recent years only a minority of 'psychopaths' have been transferred to special hospitals by this means, and most have been admitted under hospital orders (Grounds *et al*, 1987).

However, current legal provisions for the transfer of mentally disordered sentenced prisoners, although preferable, are not ideal from a criminal justice point of view. Those transferred during the course of determinate sentences can remain detained under 'notional hospital orders' at the end of sentence without any formal re-examination and renewal of detention at that time. Most of the 'psychopaths' who were transferred during sentence to Broadmoor under the 1959 Mental Health Act eventually left Broadmoor by being discharged to the community or transferred to local hospitals, but the majority of these cases were detained in Broadmoor beyond the expiry date of their original sentences before being released. Recent proposals by a Home Office & DHSS (1986) working party on 'psychopathic offenders' did not address this issue, and were motivated primarily by a concern with how to specify minimum rather than maximum periods of detention before discharge.

There is a case either for a change in clinical practice or a change in the law to ensure that sentenced prisoners given determinate sentences and transferred to hospital for treatment should normally be entitled to release at the expiry of their sentences. If continuing treatment in conditions of maximum security is required beyond this time, this should be carried out by means of making a new civil order under the Mental Health Act (S.3). This would require a new application and two medical recommendations, and would safeguard against passive continuation of detention under a 'notional hospital order' without recertification as occurs at present. Such a reform was advocated by Gostin (1977) but not incorporated into the new Mental Health Act, although it was agreed that, in the case of restricted patients, Home Office restrictions on discharge should be lifted at the "earliest date of release" (which allows for remission) rather than the "latest date of release".

Discussion

Psychiatric help and care should continue to be offered to serious offenders with personality disorders. The question raised in this paper is what is the most appropriate, realistic and just legal framework for doing so. Provisions in the Mental Health Act to transfer 'psychopathic disorder' offenders to hospital during the course of prison sentences are preferable to the use of indeterminate hospital orders, subject to improved safeguards of the right of release at the end of sentence, which are necessary from a criminal justice point of view. Psychiatric help for such offenders needs to be available, but without involving doctors in an inappropriate role and without the offenders themselves losing the right to sentencing according to 'just deserts' principles. As C. S. Lewis (1953) argued, the consequences can be inhumane if we seek to *substitute* mercy for justice. "Mercy detached from justice grows unmerciful, that is the important paradox."

In the case of 'psychopathic disorder', if there was evidence, first, that we were dealing with a well-defined disorder; secondly, that we had specific treatments for it; thirdly, that we knew who was likely to benefit from treatment; fourthly, that such treatments were effective in producing psychological change; and fifthly, that psychological change implied a reduced risk of dangerous behaviour; then there would be justification for preferring to deal with such offenders by indeterminate treatment orders rather than tariff sentencing. But the evidence at each step is lacking and is insufficient to justify the practice of recommending hospital orders for 'psychopaths'. The view that this practice is appropriate continues to be held within the English special hospital system, but it has to be questioned to what extent the beliefs that sustain this practice can be empirically supported.

Acknowledgements

I am grateful to Mrs E. Parker and Ms A. Newman of the Special Hospitals Research Unit for statistics on admissions, to Professor J. Gunn, Mrs S. Dell, Dr P. McGrath and Dr G. Robertson for discussion and comments, and to Dr J. R. Hamilton for his support and encouragement. The opinions expressed in this paper are those of the author and do not necessarily represent those of Broadmoor Hospital or the Department of Health and Social Security.

The Dismantling of the Mental Hospital?

Glenside Hospital Surveys 1960–1985

M. FORD, C. GODDARD and R. LANSDALL-WELFARE

Results of the sixth quinquennial survey of the resident population of Glenside Hospital, Bristol, are reported. The total population continues to fall, but the rate of decline has slowed; the implications of this are discussed. Many patients live in an emotionally impoverished state, friendless and rarely leaving the hospital. Few in-patients are employed, even within the hospital. Considerable provision is made, however, for the employment of day-patients. To effectively resettle and support in the community those currently remaining in hospital will require increasingly extensive provision.

Every 5 years since 1960, the population of Glenside Hospital, Bristol has been reviewed with reference to in-patients of more than 3 months' duration, and their needs for accommodation and employment (Cooper & Early, 1961; Early & Magnus, 1966; Early & Nicolas, 1971, 1977, 1981).

All of the surveys have employed the technique originally developed by Cooper & Early (1961), in which a schedule of 34 items is completed for each patient resident for 3 months or more on the day of the survey. Necessary information for this purpose is obtained from the charge nurse, case-notes and central hospital records. For the 1985 survey an extra question was added in order to identify those patients who had been in-patients at the time of the 1960 survey, the 'Remnant'.

Results and comparison with previous surveys

Figure 1 and Table I show the length of stay of patients. On 1 January 1985 there were 368 patients (175 men, 193 women) resident in the hospital for more than 3 months. Over 25 years the population has fallen from 1012, a fall of 64%.

Between 1980 and 1985 there was a fall in the population hospitalised for more than 5 years and a levelling of the numbers in the 2–5 years group. Patients resident between 3 months and 2 years increased both in percentage and absolute terms.

The population aged progressively from 1960 to 1980 (Fig. 2). Between 1980 and 1985, however, the percentage in each of the four major groups remained much the same. In 1985, 46% of men and 65% of women were over 65 years.

The legal status of patients is shown in Table II. Between 1980 and 1985, the number and percentage of detained patients increased.

Employment data are given in Table III. The latest figures show unemployment affecting over 80% of the resident population. Only a handful were working outside the hospital, despite access to a sheltered workshop. There had been a dramatic fall in those working in the hospital Industrial Therapy Workshop and other hospital departments since 1975.

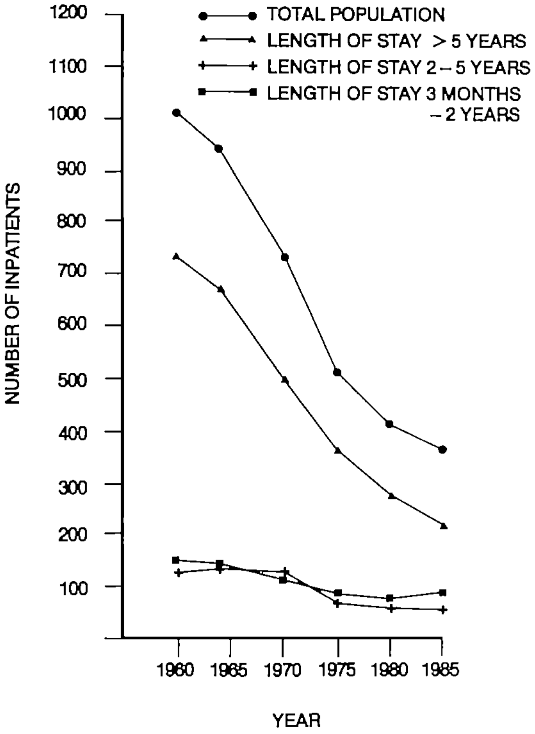

FIG. 1 Length of stay of patients in Glenside Hospital.

Information on contacts is given in Table IV. Between 1980 and 1985 there was no substantial change in the contacts that the patients had; 50% of the patients in

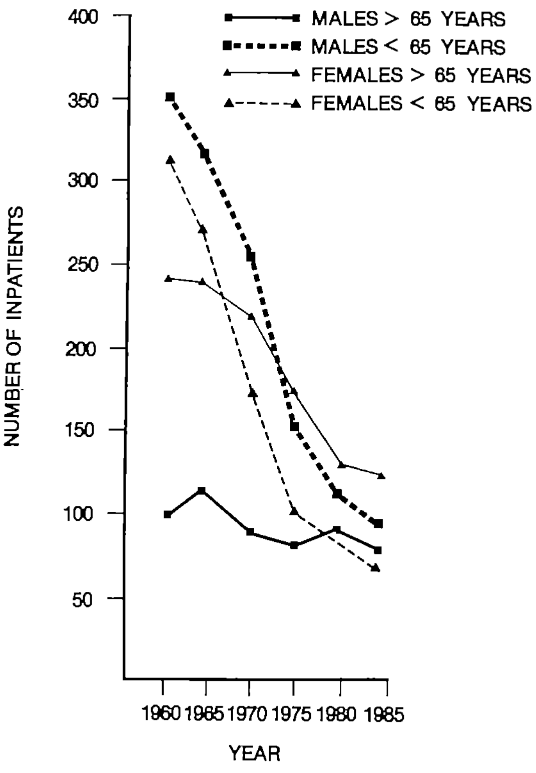

FIG. 2 Age of patients in Glenside Hospital.

hospital for more than 5 years in both 1980 and 1985 did not go out and were rarely visited.

In 1985 a significant proportion (26%) still required little or no nursing care (Table V). The proportion requiring routine geriatric care was 9%, similar to that in 1980.

In line with nursing requirements, accommodation requirements have changed little in percentage terms over the 25 years, although absolute numbers have fallen (Table VI). In 1985, 28% had no need for hospital care.

Discussion

Hospital population

Nationwide, over the period 1960 to 1985, the number of in-patients fell from 128 000 to 64 000 (General Register Office, 1964; DHSS, 1986), a fall of 50%. Glenside has been in line with or slightly in advance of this trend. However, the rate of decline of the total Glenside population appears to be slowing. Between 1960 and 1980 the decline averaged 3% per annum, and from 1980 to 1985 the fall was 2% per annum. These figures have implications for planning and are further evaluated under attrition rate.

The small increase in the number of detained patients may reflect the interests of the consultants and the absence of a medium-secure unit in Avon. (A medium-secure unit is planned for the Glenside site.) Detention is far less used than in 1960.

The age structure of the population remains much the same as in 1980. There continues to be an increase in the very elderly: in 1985, 30% were over 75. The main feature of the period 1975 to 1980 was an increase from 35% to 44% in men aged over 65. This has slowed considerably – 2% increase from 1980 to 1985. Since 1980 there has been a small rise in the under 45 age group: in 1985 it was 14% of the total.

The number in the group resident more than 5 years has fallen, but is still substantial. The diagnostic categories are little changed since 1980: the latest figures give 76% schizophrenic and 5% with senile dementia. This latter figure reflects the life expectancy of severely demented hospital patients who 'because of the high mortality rate . . . are resident for less than five years' (Wing, 1979). However, it should be noted that 10 of the 65 demented patients in our study had lived in hospital for more than 5 years.

In the 2–5 year group, the numbers in 1980 with a diagnosis of dementia or schizophrenia were approximately equal (21:20). The 1985 survey shows a marked change, 30 with dementia and 13 with schizophrenia, and there was no corresponding increase in any other diagnosis. This, if not a random change, could represent more active rehabilitation and discharge of schizophrenics.

The increase in the group resident from 3 months to 2 years is interesting. It is mainly explained by an increase in the number of patients with affective psychosis: from 12 in 1980 to 23 in 1985. There is also an increase from 0 to 6 in 'other psychoses', covering non-organic, non-schizophrenic and non-affective psychoses. These data could suggest a change in diagnostic habits rather than an increased incidence, or increased difficulty in rehabilitating these patients.

Further examination of the group resident for 3 months to 2 years revealed that two-thirds were women. This group was represented in all age brackets, 46 being under 65 years. A large number – 15 – were detained. When compared with the total resident population, a much larger percentage were or had been married. The majority – 56 – had previously been employed. Diagnostic categories were as follows: senile dementia 27, schizophrenia 22, affective psychosis 23, other psychoses 6, neurosis 3, personality disorder 5, and 5 with other diagnoses. They were more likely than other residents to be considered suitable for discharge to supervised and unsupervised accommodation, or to accommodation already available. However, only in 28 was no disturbance thought likely to ensue on discharge. Further, the chronicity of some of the group is indicated by the fact that eight of them had been in-patients in the original census of 1959. Thus, although some of this group will be discharged, they are also likely to be readmitted.

Unemployment

Unemployment is clearly and increasingly the norm. To a large extent, the 1985 figures reflect a redefinition of the role of the Industrial Therapy Department, which has now been renamed the Integrated Rehabilitation Workshops (IRW). It now offers a mixture of industrial training and occupational therapy. In-patients are clearly involved in the latter.

Increasing numbers of day-patients are attending and are considered for industrial training. Thus the IRW and the Bristol Industrial Training Organisation, situated off the hospital campus, are mainly community resources. If patients are capable of industrial training or sheltered work, then, with rare exceptions, they are living in the community. This is in contrast to 1960, when industrial training and sheltered workshops were considered the pathway to discharge for psychiatric hospital patients 'to hold their own in the community' (Cooper & Early, 1961).

By 1971, Early (1978) had commented: 'the continuation of economically viable industrial therapy in hospital will increasingly depend on the attendance of day patients.' Several major factors are operating: the ageing of the hospital population, the increasing level of general unemployment, and partly consequent on these, changing concepts of rehabilitation priorities. As a result, activities of daily living and socialisation are increasingly emphasised, and employment for the resident psychiatric in-patients is rarely an immediate goal. Also, to quote Bennett (1981), 'the appreciation that further long-stay hospital patients are being replaced by long-term patients in the community and the recognition of these disabled patients need for support together with medical and social aid, leads in turn to a reconsideration of the function of a psychiatric unit for disabled patients in a district service.'

Friendlessness

The number of patients who neither go out nor are visited remains scandalous. Factors which had a major bearing on this were male sex, marital status (only 51 were married), increasing age, and increasing duration of stay. Only 27 of 206 patients over 65 years of age went out, and of 131 patients in hospital over 20 years' duration, only 15 went out. Families 'forget' the patient; and 'society seals up its cracks against the mentally disabled' (Morgan & Cheadle, 1981).

Nursing levels are only rarely sufficient to organise trips out. The current state of affairs clearly underlines the implausibility of discharging long-term or elderly psychiatric hospital residents to a friendless world. There is a great need for an increase in staff levels and voluntary aid to re-establish contacts and interests outside the hospital.

Dementia and nursing care

The percentage of demented patients has increased only marginally; the 1985 figure is 18%. However, they have become less mobile and more dependent: the figures show 30 as permanently chairfast, 36 as considered suitable for psychiatric hospital care, and 32 for geriatric hospital care.

There may well be considerable national variation in the number of hospitalised demented patients. Levene *et al* (1985), in their study of all 1087 patients who were in psychiatric beds provided by a large district health authority, calculated that 'one third of the total . . . had a primary diagnosis of dementia.'

This inappropriate use of scarce psychiatric nursing experience continues to be a source of frustration and demoralisation to nursing staff already faced with considerable understaffing and difficulties in recruitment.

Mental handicap

There has been a continuing decline in the numbers with a primary diagnosis of mental handicap: 44 (9%) in 1975, 19 (5%) in 1980 and 5 (1%) in 1985. Of these five, four had no subsidiary diagnosis but had been hospitalised for over 20 years, and therefore were not considered for transfer to a mental handicap hospital. They are, nevertheless, inappropriately placed.

Accommodation

The numbers have fallen, but the pattern of demand for accommodation has changed little over the years. In 1985 there were still 28% who did not require hospital accommodation (37% in 1960). The major hurdle to discharge remains the lack of supervised after-care. Of the 79 patients felt to require supervised after-care, 49 had a diagnosis of schizophrenia, and 14 of affective disorder; 52 were under 65 years of age. Attempts by the hospital social work department to set up hostels under joint funding arrangements have failed, and projects from local social service departments and voluntary agencies have yet to show themselves able to take anything but a small proportion of the problem.

The characteristics of the patients in this survey suggest that they will require not just supervised accommodation but also the full range of day-care facilities. To quote Wing & Morris (1981): 'The very success of the rehabilitation programmes of the 1960's and 1970's has meant that the population left behind in hospital was increasingly handicapped', and resettlement required 'an extensive network of sheltered residential and day units'.

However, the contrast with 1960 remains clear, for the Glenside survey of that year illustrated 'the immediate need for aftercare accommodation for over 300 patients, many of whom have been in hospital continuously for several years and have only mild psychiatric symptoms' (Cooper & Early, 1961).

Moreover, there has been a considerable sum spent on residential accommodation and supportive services for the elderly mentally infirm outside of hospital. Additionally, there has been a recent mushrooming of private-sector accommodation for the elderly. Thus, while the percentage of Glenside patients with dementia has increased, this has only been a fraction of the total in the community. In other areas, as referred to earlier, the psychiatric hospital may be providing accommodation for a much larger proportion of the demented.

The Remnant

The Remnant is a group of 112 patients who in 1985 had been continuously in-patients since the first survey in 1960. These were compared with 38 patients who had been in-patients in 1960 but had had at least one intervening period out of hospital since.

Similarities between the groups include the predominance of schizophrenia, poor social participation, present unemployment, and siblings being the only potential outside support.

Differences include the predominance of males in the continuous group (67 men, 45 women) compared with an equal sex ratio in the discontinuous group. This could lend support to the evidence for a more favourable prognosis for women, which has been consistently noted in modern studies of schizophrenia (Watt & Szulecka, 1979; Watt *et al*, 1983; Hogarty *et al*, 1974).

Compared with the discontinuous group, the remnant were older, more likely to be unmarried, more obviously mentally abnormal, more likely to be considered of below average intelligence, and less likely to have contacts with the outside world.

Interestingly, there was an excess in the Remnant of those who had held regular semi-skilled or unskilled work prior to admission. As to those who had held skilled work, the proportions in each group were similar. In the discontinuous group, 25 of the 38 had been unemployed on admission, compared with only 45 of the 112 of the Remnant as a whole ($P=0.01$). We presume that this reflects the predominance of men in the Remnant, and the effects of previous psychiatric admission in the discontinuous group. It also points to the catastrophic nature of some schizophrenic illnesses, leading some people directly from employment to permanent hospital residence.

The Remnant therefore consists of nearly one-third of the hospital population. They are generally over 55 years old, male schizophrenics, with poor social functioning and few outside contacts. These severely handicapped people continue to live in impoverished ward environments with only minimal staff. They also suffer personal poverty, no longer being able to supplement their income from industrial therapy; they survive on a basic allowance which scarcely provides a packet of cigarettes a day. One could envisage that increased resources would improve their lives, but the prospects of them participating in the 'community' must be limited.

Attrition

One can note that 'in districts which are still served by a mental illness hospital there may be little value in distinguishing between "new long stay" and "old long stay" patients; for planning purposes, what is needed is a statistical calculation of possible future bed requirements from the rate of decline in both groups (either taken separately or together)' (DHSS, 1985).

The current rate of attrition of those in hospital more than 5 years is 12 per annum. At present rates this group will not disappear by death or discharge until 2003. By comparison, a similar calculation in 1980 postulated extinction of the group by 1996.

Calculation of accumulation rate in the 2–5 years group, after removing those with dementia and organic psychosis, most of whom will die within 5 years of admission, reveals a rate of 9 per annum. Life expectancy tables for this group, average age 66 years, indicate a life of 15 years per patient. This group will, therefore, eventually need 135 beds. Excluding dements and those staying less than 2 years, bed requirements for long-stay patients would level out at 135 in 2003. However, both the excluded groups (i.e. the demented (30) in the 2–5 years group and the whole of the 3 months to 2 years group (91)) are currently increasing.

Various predictions of the 1955 population were made by (a) extrapolation of the total population curve visually, (b) dividing into age and sex groups and using similar extrapolations, and (c) using life expectancy tables for the various groups of duration of stay. These methods predicted 284, 301 and 298 respectively. The mean of these is 294 – a fall of 74 patients over 10 years, or approximately 2% per annum. Thus the hospital population will continue to fall, but at a slower rate.

Conclusion

Employment, even sheltered, is no longer a major feature of in-patient care. As the hospital population ages and national unemployment increases, the values and skills developed by occupational therapists are considered more relevant than industrial therapy. However, for patients residing in the community, industrial therapy continues to be regarded as an essential part of rehabilitation.

The hospital population continues to fall, but the rate of decline is slowing. Predictions suggest that this deceleration will not be reversed. This is particularly relevant at a time when the Department of Health and Social Security claim that 'it is increasingly urgent for regions to decide on a regional strategy for psychiatric services, including hospital closure where relevant' (DHSS, 1981).

If the concepts of community are applied to our resident population, their characteristics suggest that they will need supervision, day care, extensive rehabilitation, and friends in the community. Many will also require periods of psychiatric hospital care.

The slowing in hospital population decline suggests that, except for the demented, increasingly appropriate facilities have not been developed. Of central importance 'is the absence of the necessary infrastructure for services and the financial supports without which talk of community care is surely a sham' (Scull, 1983).

Acknowledgements

Our thanks go to all the nursing staff who helped collect the data. Our thanks also to Dr M. Nicolas for encouraging us to repeat the survey, and to Mr Alan Hayward, Top Grade Clinical Psychologist, for the statistics and help with data analysis.

The Extent and Nature of Depressive Phenomena in Primary Health Care

A Study in Calcutta, India

BISWAJIT SEN and PAUL WILLIAMS

The extent and factor structure of depressive phenomena were investigated in three primary health care clinics in the city of Calcutta. The Self-Reporting Questionnaire and the Screening for Depression Questionnaire were used as the first-stage instruments, and the Clinical Interview Schedule and the Hamilton Rating Scale for Depression as the second-stage instruments. The implications of the findings are discussed.

Around 3% of the global population were estimated to be suffering from some form of clinically recognisable depression a decade ago (Sartorius, 1974). If the definition of depression is extended to include depressive phenomena of any degree of severity, estimates given by Shepherd (1983) allow one to calculate that around 15% of the (British) population are so affected. Studies quoted by Kapur & Singh (1983) and Venkoba Rao (1984) reveal that clinically recognisable depressive disorders are as common in India as in the Western world; they were estimated to affect 3–5% in community surveys carried out in the last decade.

Naik & Wig (1980), in a study conducted as part of a larger World Health Organisation investigation in a general hospital out-patient service in Chandigarh in North India, concluded that "about 20% of the cases seen in a general medical practice" exhibit depressive phenomena "with or without other physical illnesses". General practitioners carried out the first-stage screening, with the WHO-SADD (Standardised Assessment of Depressive Disorder; WHO, 1983) being applied to detect depression. Though the socio-demographic profile of the clinic attenders was not provided, it may be assumed that they largely belonged to the lower social classes, from the lower middle class downwards (since this is characteristic of attenders at hospital clinics, where no fees are charged).

Most people suffering from depression are not seen by psychiatrists. Many present themselves to primary care clinics (Shepherd, 1983; WHO, 1975), often with vague somatic problems. It is believed that this is particularly true for developing countries like India where there is a shortage of specialist psychiatric facilities. The overwhelming majority of these patients are not recognised as suffering from depression and thus remain untreated. An important reason for this situation may well be the lack of adequate mental health education of primary health care personnel. This in turn is believed to be, at least in part, due to lack of sufficient knowledge on the nature, frequency, and management of depressive disorders in primary care.

The present study was conducted in Calcutta, in the eastern part of India, in areas housing predominantly pre- and semi-literate people belonging to the lowest socio-economic classes. One of the original objectives of the study was to investigate the extent to which health auxiliaries with limited training were successful in detecting psychiatric morbidity in general, and depressive illness in particular (Sen *et al*, 1987). The present paper, however, is concerned with the following aims: (a) to assess the extent of depressive phenomena in this setting; (b) to explore the nature of depressive phenomena with the aid of factor analysis, and their relationship to anxiety.

Method

Study area

Three primary care clinics situated in the periphery of the city of Calcutta were chosen for the study. A notable feature of these clinics was that all three were situated within small catchment areas of between 3000 and 5500 persons, and more than 90% of the residents in each area were registered with the corresponding clinic. The majority of patients attending these clinics were manual workers living in slums or crowded housing, with primitive sanitary conditions.

Research instruments

Screening for Depression Questionnaire

The SDQ was constructed in Bengali for the purposes of this study. The ICD-9, DSM-III, and WHO-SADD were taken into consideration for the development of this questionnaire. It consists of nine questions designed to elicit symptoms commonly found in almost any variety of depression by means of simple Yes/No answers. The SDQ was designed to be either self-administered or, with pre- or semi-literate persons, to be administered by health auxiliaries.

Self-reporting Questionnaire

The SRQ-20 (Harding *et al*, 1980) was also designed to be either self-administered or given by health auxiliaries, and has been extensively used in developing countries (Harding *et al*, 1983).

Clinical Interview Schedule

The CIS (Goldberg *et al*, 1970) is a standardised, semi-structured inventory designed for use in community surveys and general practice studies. Its feasibility and reliability have been tested in many settings across different cultures (Goldberg *et al*, 1970; Campillo-Serrano *et al*, 1981; Cheng *et al*, 1982; Mari *et al*, 1986). It is administered by a psychiatrist trained in its use, and enquiries about ten groups of 'reported' symptoms and twelve 'manifest' abnormalities are rated along five-point scales.

Hamilton Rating Scale for Depression (HRSD)

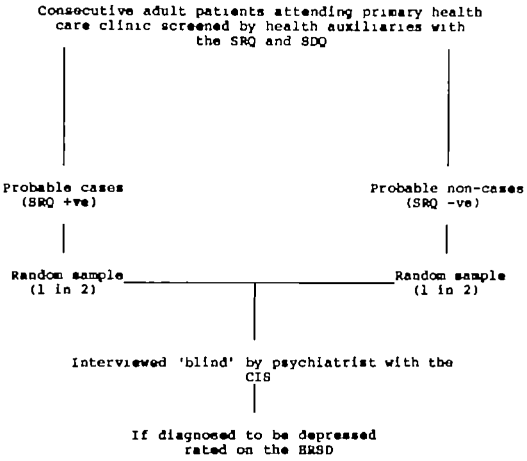
The Hamilton scale (Hamilton, 1967) is probably the most widely used depression scale in clinical research. It is designed for quantifying the results of a clinical interview with patients diagnosed as depressed. An 18-item version was used, with 'paranoid symptoms' added to the generally used 17-item scale. A score of 20 or above was held to be indicative of depression (Bech, 1981).

Translation

The SRQ and the CIS were translated into Bengali by the senior author and back-translated into English by a schoolteacher not acquainted with the original versions. The back-translation was subsequently compared with the original version jointly with an English psychiatrist for conceptual equivalence of the items. Minor modifications were made to the translated questionnaires to remove discrepancies.

Collection of data

The design of the study is illustrated in Fig. 1. An unduplicated consecutive series of adult patients (15 years and above) attending the three primary care clinics over a period of four weeks (in July and August 1985) were screened by health auxiliaries with the SRQ and the SDQ. Those who scored 8 or above on the SRQ were designated as 'probable cases' and those with scores of 0–7 as 'probable non-cases'. The psychiatric interview was conducted 'blind' (i.e. without knowledge of the questionnaire responses of the individual).



Consecutive adult patients attending primary health care clinic screened by health auxiliaries with the SRQ and SDQ
Probable cases (SRQ +ve)
Probable non-cases (SRQ -ve)
Random sample (1 in 2)
Random sample (1 in 2)
Interviewed 'blind' by psychiatrist with the CIS
If diagnosed to be depressed rated on the HRSD

FIG. 1 Design of the study.

Personnel and training

Three health auxiliaries who had between 8 and 12 years of schooling and were subsequently trained in primary health care were involved in the study. Two were members of the respective communities. They received no particular training apart from a 30-minute orientation session, during which it was ascertained that they themselves understood the questions and the procedure that was required of them. In situations of doubt regarding the presence or absence of the symptom, they were asked to score the symptom as present.

Results

Two patients were so ill that it would not have been feasible to administer the research questionnaires. There were no refusals.

Characteristics of the sample

Out of the total sample of 202 respondents, 48 (24%) were males and 154 (76%) were females. As would be expected in India, almost half the patients were between 15 and 35 years of age. More than a third of the population could not read or write, and only 12% were educated beyond primary school. The average per capita annual income of the population was below Rs1200/-; that is, around $100 (the national average is around $270, according to the 1981 census).

The two questionnaires were administered by the health auxiliaries to 202 consecutive adult attenders, out of whom 114 were interviewed. The interviews were conducted almost immediately after administration of the questionnaires.

Validity of the SDQ

The validity of the SDQ in this sample has been described in detail elsewhere (Sen & Williams, 1987). It was observed that although the sensitivities of the SDQ both against the 'Manifest Depression' items of the CIS and against the Hamilton scale were high (83% and 88% respectively), the specificities (60% and 51%) and positive predictive values (47% and 43%) were low. In search for a better predictor, it was found that a new nine-item questionnaire (SDQ-9; see Table III), constructed from items in the SRQ and SDQ which discriminated most successfully between depressed and non-depressed individuals, had higher validity indices against the two measures of depression (Table I).

TABLE I
Validity indices of SDQ-9

	Manifest Depression	*Hamilton*
Sensitivity: %	77	87
Specificity: %	79	51
Positive predictive value: %	59	43

Extent of depressive phenomena in primary care

Out of 48 males, 13 (27%) scored more than 5 (the cut-off point) on the SDQ-9, 14 (29%) were judged depressed by the Manifest Depression items, and 5 (10%) by the Hamilton scale. Table II shows the estimated number (with percentages) of females of different ages exhibiting depressive phenomena when interviewed with the three scales. It is obvious that an estimate of depressive phenomena varies with the stringency of the applied criteria.

TABLE II
Number of females with scores >5 in SDQ-9, and estimates of the number of females with positive scores in Manifest Depression and in Hamilton, by age (figures in parentheses are age-specific percentages)

Age groups	*Females (n = 154)*		
	SDQ-9	*Manifest Depression*	*Hamilton*
15–24	9 (26)	5 (14)	5 (14)
25–44	38 (54)	42 (59)	23 (32)
45–64	25 (71)	18 (51)	10 (29)
65+	5 (39)	7 (54)	4 (31)
All ages	77 (50)	72 (47)	42 (27)

In the females, it is seen that, as a whole, more than a quarter of all the respondents suffer from marked depression, as judged by the Hamilton scale. It is also observed that the proportion of depressed respondents varies little between the three older age groups, whether judged by the Manifest Depression items or the Hamilton scale. The proportion exhibiting depressive *symptoms* (SDQ-9 score >5), however, increases markedly in the 45–64 age group.

TABLE III
Frequency of positive replies on the SDQ-9 items in males and females

SDQ-9 items	*Males (n = 48)*		*Females (n = 154)*	
	Number	*%*	*Number*	*%*
1. Do you feel unhappy?	28	58	110	71
2. Do you have trouble thinking clearly?	21	44	96	62
3. Do you find it difficult to make decisions?	19	40	89	58
4. Is your daily work suffering?	25	52	76	49
5. Do you see little hope for the future?	20	42	106	69
6. Have you ever thought 'What is the use of carrying on any longer?'	16	33	88	57
7. Are you unable to play a useful part in life?	24	50	93	60
8. Do you feel that you are a worthless person?	19	40	86	82
9. Has the thought of ending your life been in your mind?	6	13	36	23

The frequency of positive replies to the individual items of the SDQ-9 are shown in Table III. A remarkably high proportion of both males and females appear to suffer from each of the nine depressive symptoms. The proportion of females is greater than males in every item except "daily work suffering". However, except for the question on "worthlessness", to which the females answer "yes" twice as often as men, the differences are not as much as would be expected. It is remarkable that more than three-quarters of the females felt "worthless" and more than two-thirds admitted to "unhappiness" and "hopelessness". It is also interesting that almost a quarter of the women admitted to suicidal ideas.

Factor structure of depressive phenomena

A principal components analysis with varimax rotation was carried out to explore the structure of depressive phenomena in the primary health care setting. The procedure yielded three factors for the SDQ (Table IV) and two for the SDQ-9 (Table V). Items with factor loadings of less than 0.5 were disregarded, as it is generally agreed that such items are found less consistently under the same factor across populations.

Among the three factors isolated from the SDQ, factor I may be said to represent a vignette which is familiar to clinicians in India as one of the typical pictures of depression

TABLE IV

Principal components analysis with varimax rotation of SDQ

	Factor loading
Factor I	
(25.7% variance explained)	
Think it is better to die	0.721
Inner restlessness	0.719
Hopeless	0.653
Sad	0.556
Lack in self-confidence	0.532
Factor II	
(12.9% variance explained)	
Guilt	0.655
Crying	0.645
Factor III	
(12.6% variance explained)	
Loss of interest	0.732
Sad	0.550
Weak	−0.504

(Wig *et al*, 1980). However, factors II and III cannot be clinically conceptualised with ease as separate entities, and hence are difficult to interpret in the Indian context as meaningful subgroups of depression. This is not surprising as three of the five items constituting the two factors, namely "guilt", "loss of interest", and "weak", were among the poorest discriminators for depression in an item-by-item analysis.

In contrast, both the factors isolated from SDQ-9 seem capable of a sensible interpretation. Items in factor I are mostly general in nature and may be expected to predict relatively mild depression, perhaps including even 'normal' depression. Items in factor II would be expected, on the other hand, to predict depression of a marked degree. Such an interpretation is suggested by the fact that the positive predictive value of factor II against the Hamilton scale (which is assumed to indicate depression of a marked degree) is the same as that of the SDQ-9 as a whole (52%, calculated for 30% prevalence). In contrast, the positive predictive value of factor I against the Hamilton scale is lower than that of the SDQ-9 (46.9%).

TABLE V

Principal components analysis with varimax rotation of SDQ-9

	Factor loading
Factor I	
(39.1% variance explained)	
Unable to play a useful part in life	0.790
Worthless	0.643
Daily work suffering	0.639
Cannot think clearly	0.584
Difficulty in making decisions	0.573
Unhappy	0.516
Factor II	
(11.4% variance explained)	
Think of suicide	0.824
Think it is better to die	0.792
Hopeless	0.505

Relationship of depressive with other psychiatric phenomena

Since the SRQ contains questions related to psychiatric phenomena other than depression, it was decided to

TABLE VI

Principal components analysis with varimax rotation of the SRQ

	Factor loading
Factor I	
(21.8% variance explained)	
Unhappy	0.745
Anxious/tense/worried	0.680
Unable to play useful part in life	0.507
Factor II	
(7.8% variance explained)	
Lost interest	0.768
Crying	0.623
Think of suicide	0.513
Factor III	
(6.5% variance explained)	
Easily frightened	0.737
Headaches	0.556
Cannot think clearly	0.511
Factor IV	
(6.1% variance explained)	
Cannot enjoy daily activities	0.751
Cannot think clearly	0.507
Difficulty in making decisions	0.506
Factor V	
(6.0% variance explained)	
Poor digestion	0.818
Abdominal discomfort	0.810
Factor VI	
(5.5% variance explained)	
Poor appetite	0.681
Sleep badly	0.680
Factor VIII	
(5.3% variance explained)	
Easily tired	0.812
Constantly tired	0.739

investigate the relationship of these phenomena with depression, with special reference to those related to anxiety. A principal components analysis with varimax rotation isolated seven factors (Table VI).

It may be noted that factor I, which may be conceptualised as an anxiety-depression component, explained 21.8% of the variance. Each of the other six factors explained between 7.8% and 5.3% of the variance. It is observed that there is no clearly defined separation between depression, anxiety, or somatic phenomena in any of the factors.

Since factor I, which contains the most direct of the three questions on anxiety, explained more than a fifth of the variance and also discriminated moderately well between depressed and non-depressed respondents on the Manifest Depression items and the Hamilton scale (Sen & Williams, 1987), it was decided to explore further the relationship between depression and anxiety.

Out of 114 respondents interviewed, 32 (28%) had clinical anxiety, all of a mild nature. All but five of them were judged to be suffering concurrently from depression.

The three anxiety items on the SRQ, namely "anxiety/tension/worry", "easily frightened", and "hand tremor", were taken together, and validity indices of this new scale (termed SRQ-Anxiety) were obtained against the "manifest" anxiety scale of the CIS (termed Manifest Anxiety) as well as against Manifest Depression. Indices of validity were also obtained for SDQ-9 against Manifest Anxiety for comparison. The indices are shown in Table VII.

TABLE VII

Exploring the relationship between depression and anxiety: validity indices of SRQ-Anxiety against Manifest Anxiety and Manifest Depression, and SDQ-9 against Manifest Anxiety

	SRQ-Anxiety v. Manifest Anxiety	*SDQ-9 v. Manifest Anxiety*	*SRQ-Anxiety v. Manifest Depression*
Sensitivity: %	43.8	59.3	52.2
Specificity: %	70.7	72.0	78.6
Positive predictive value (adjusted for prevalence): %	48.7	57.5	60.5

It is evident that the SDQ-9, which does not contain any question to detect clinical anxiety, is superior to SRQ-Anxiety in screening for anxiety. It is also interesting that SRQ-Anxiety performs better in screening for depression than it does for anxiety.

Discussion

Extent of depressive phenomena in primary health care

Studies reporting the extent of depression in primary health care in India are few. As indicated earlier, Naik & Wig (1980), using WHO-SADD as the second-stage instrument, studied the prevalence of depressive symptoms in a general medical practice in Chandigarh and found that around 20% of the clinic attenders had depressive symptoms. Reviewing available literature, Venkoba Rao (1984) estimated that the prevalence of depression in general medical practice varies from 5% to 25%, depression being "four to five times more in northern and eastern India" than in the south and west. In a rural primary health care clinic not far from Calcutta, Banerji *et al* (1987) reported that in a sample of 80 adults who had been attending regularly for at least six months, the prevalence of depression, as judged by clinical interview, was 20%.

In the present study, clinically recognisable depressive phenomena, ranging in intensity from mild to marked, is estimated to occur in 42.6% of the respondents (proportion positive on Manifest Depression), with 23.3% being diagnosed as suffering from depression of marked intensity (proportion positive on Hamilton). Over a quarter of the women (27.3%) of all ages were estimated to be depressed on the Hamilton scale.

Informal enquiry among the 'Hamilton positive' women in the interviewed subsample revealed that none of them were under psychiatric care, a finding which is not surprising in this setting. While they were obviously aware that their 'illness' merited medical attention, they apparently did not consider that the 'illness' was a potentially treatable psychiatric condition. The medical officers in charge of the clinics reported that, while they suspected that a section of their patients might be depressed, they thought this to be due to their adverse socio-economic and, perhaps, family circumstances, factors which they felt to be beyond their control, especially in view of their "chronic patient overload". This situation is believed to be representative of the Indian context. Thus the responsibility for the treatment and care of these individuals may be expected to devolve upon the health auxiliaries (rather than mental health professionals), who, of course, have to be appropriately trained for the purpose.

Among Western studies, Stoeckle *et al* (1964) interviewed 101 "new patients" coming to the medical clinic of the Massachusetts General Hospital and found "depressive reactions" in 59.4% (men 49%, women 69%). Hoeper *et al* (1979) studied the prevalence of psychiatric disorders in Marshfield Clinic in Wisconsin, and applying SADS-L criteria, estimated that 14.2% of a sample 1072 patients who consented to participate in the study (there were 255 refusals) were suffering from depressive disorders.

Parker *et al* (1984) applied PSE criteria to 564 subjects, predominantly women, attending "representative (general) practices" in Sydney: they calculated that at least 18% had depressive disorder. Skuse & Williams (1984) estimated that 26% of all the patients attending a general practice in London were depressed. Their diagnosis was based on joint rating of a structured clinical interview.

Generalising from these studies in India and the West about the prevalence of depression in general practice/primary health care studies may not yield precise estimates because of the cultural, social and demographic differences between the populations, and also because of the different diagnostic criteria used. However, two trends are readily observed. It appears that, with hospital-oriented criteria, between one-sixth and one-fifth of primary health care clinic attenders are diagnosed as depressives. With less stringent criteria, more suited to the primary health care situation, between two- and three-fifths of the attenders are seen to manifest depression.

In Table II, the sudden and marked increase in the proportion of women between the ages of 45–64 years exhibiting depressive symptoms (SDQ–9 score >5) is difficult to interpret. Certainly the phenomenon needs to be replicated in other studies before a proper evaluation can be carried out. A possible explanation may be an exaggerated emotional response to somatic disorders at a period of life when physical stamina is on the decline, with no corresponding reduction in day-to-day responsibilities, which mostly require manual labour. Clinically, this period of life is associated with an increased frequence of consultation for minor physical complaints. If the excess of 'depressive' complaints is seen to be restricted to the clinic setting, the explanation offered would receive support.

It can also be noted in this context that certain life events which may predispose to depressive symptoms are common during this period (e.g. children getting married and leaving home; husband's retirement, with consequent reduction or loss of regular income). It needs to be investigated whether this phenomenon is also observed in community studies in similar settings.

Nature of depression in primary health care and the relationship with anxiety

SDQ–9

The clinical interpretation of factors I and II (obtained from SDQ–9, Table V) as 'mild' and 'marked' depression respectively has been mentioned. It is not claimed, however, that these are distinct categories. On the contrary, the finding that factor I ('mild depression') discriminates between Hamilton positive and negative individuals with a fair degree of accuracy lends support to the dimensional view of depression rather than the categorical. It may be that factor I is representative of individuals with 'distress states' which do not require physical forms of treatment like tricyclics and ECT. Indeed, it is possible that the majority of individuals experiencing similar states discontinue prescribed tricyclics within a few days of commencement because of 'intolerable' side-effects. Factor II appears more likely to be representative of individuals who would benefit from drugs and ECT. It is planned to test this hypothesis in the near future in one of the clinic areas.

The relationship between depression and anxiety has recently been reviewed by Stavrakaki & Vargo (1986). They noted issues such as the presence of mixed anxiety and depression, and contradictory research findings, and suggested that "there is no unequivocal solution to the problem of how anxiety and depression are related". While most of the studies they reviewed were from Western countries, Leff (1981) noted that in India also there is a considerable degree of overlap between patients' concepts of anxiety and depression, a view which finds support in the present study. However, the findings of this study allow this notion to be taken further. It is possible that the reason for the overlap is that anxiety is found most often as a concomitant of depression and is thus necessarily highly correlated with the latter. The inability of respondents to distinguish between depression and anxiety could possibly be attributed to the same cause.

The undifferentiated nature of different psychiatric phenomena

Principal components analyses with varimax rotation of GHQ–30 and GHQ–60 data have been reported in many studies (see the review by Vieweg & Hedlund, 1983). Most of these have revealed an anxiety–depression/dysphoria component which explained 20–25% of the total variance. Two studies, both using the GHQ–60, have reported this component explaining over 50% of the total variance (Worsley *et al*, 1978; Chan & Chan, 1983).

To our knowledge, this is the first occasion on which the factor structure of the SRQ has been reported (Table VI). It is suggested that factor I, which explains 21.8% of the variance, corresponds with the anxiety–depression/dysphoria component of the studies quoted above. While a case may be made out, in the light of this finding, in favour of the universality of an anxiety–depression syndrome in primary health care and community studies, the present situation is seen to be more complex from an examination of the other factors isolated from the SRQ. Whereas in the studies reporting the factor structure of the GHQ the several factors could be conceptualised with relative ease, factors II to VII do not readily lend themselves to clinically meaningful interpretation. The lack of clear separation of the various psychological and somatic dimensions suggests that much of the psychiatric morbidity in primary health care is undifferentiated, a view similar to those expressed by Shepherd (1977).

Clinicians in India are familiar with the generally undifferentiated nature of the complaints expressed by patients, particularly those coming from the lower social strata. Not infrequently, even experienced psychiatrists, thoroughly familiar with the subculture represented by the patient, are hard put to place the subject in an appropriate diagnostic category. This may be appreciated from the coining of a term, possibly arising more out of a sense of desperation than any attempt at clarification, such as 'panneurosis'.

The factor structure of the SRQ, with special reference to the relationship between depression and anxiety, has particular relevance for the classification of minor psychiatric disorders in the primary health care settings in India. The essentially undifferentiated nature of the symptom patterns suggests that narrowly defined criteria of the various neurotic disorders familiar to clinicians will serve little purpose in these settings. This study has shown that health auxiliaries are able to diagnose depressive disorders with some degree of confidence. The detection and nature of other types of psychiatric phenomena must remain, for the present, objects of further epidemiological research.

Conclusion

The essential objective of this paper was to explore the extent and nature of depressive phenomena in the primary health care setting in India, with reference to their relevance to health auxiliaries with limited training. The importance of diagnosing depressive disorders in primary health care clinics has been established. The extent to which health auxiliaries can be successful in treating such disorders now needs to be studied. The long-term view must, of course, be that of exploring the means whereby health auxiliaries can succeed in preventing their occurrence. This, perhaps, is not as distant a goal as it appears at first sight. The societal structure in India is generally held to be orientated strongly towards the extended family, which is held together by strong cohesive forces. The potential for emotional support which exists within the extended family is an important resource for patients with minor psychiatric disorders (Aneshensel & Stone, 1982). And the person who is ideally suited to mobilise this resource, being the health professional closest to the family, is the health auxiliary. With suitable training and education (Wig *et al*, 1981), the health auxiliary should be able to play a cardinal role in the management of psychiatric morbidity in primary health care settings in the foreseeable future.

Acknowledgements

Acknowledgements are due to Mr A. Larsen, Director, Lutheran World Service (India) for permission to conduct the study in clinics under his administration; and to the three health auxiliaries, Mrs Lakshmi Das, Miss Anjali Dey and Mr Sankar Saha, for their co-operation. We thank Professor Michael Shepherd for comments and suggestions concerning the paper, Mrs Nandini Dasgupta for the translation of the screening questionnaires, and the anonymous referees for their helpful comments.

Biswajit Sen was supported by a scholarship from the Stromme Memorial Foundation of Norway.

Psychological Intervention in Civilian Flying Phobia

Evaluation and a Three-Year Follow-Up

C. P. WALDER, J. S. McCRACKEN, M. HERBERT, P. T. JAMES and N. BREWITT

Thirty-eight people with a moderate to severe degree of aerophobia self-referred themselves to a course designed to help them travel by air. The course involved three long sessions based on giving information, graded exposure without avoidance, and group support with natural coping models. Measures of self-reported anxiety levels were taken at regular intervals. The results showed that being given information or undergoing a simulated flight had little effect on perceived anxiety. Prolonged exposure to flying had a marked effect on reducing anxiety and anticipated apprehension about future flying. At one-year and three-year follow-up, 40% and 60% of participants had flown commercially, although there was some minor restoration of anticipated anxiety associated with flying; 84% showed less anxiety about flying. Psychological intervention, in collaboration with airlines, may have marked benefits in reducing fear of flying.

Many people are apprehensive about air travel. Agras *et al* (1969), in an epidemiological study of phobias, reported fear of flying to be intense in 10% of the population and mild in 20%. For some, the anxiety associated with such travel causes psychological and/or physiological symptoms severe enough to prevent the sufferer from flying. In consequence, social life, vacations or job opportunities may be impaired.

Most of the research into the treatment of phobic reaction to flying has concentrated on military personnel and trained air crew (Anderson, 1948; Morgenstern, 1966; Goorney, 1970; Aitken *et al*, 1970; O'Connor, 1970; Daly *et al*, 1970; Aitken *et al*, 1981). Anderson (1948) believed that "the prognosis is usually bad". Morgenstern (1966) concluded that there was no successful treatment for USAF personnel, although Goorney (1970) did note flying phobia to be a treatable condition. This was confirmed by Aitken *et al* (1970) when, as a result of using a combination of behavioural strategies together with psychotherapy, 9 out of 14 aircrew were able to return to limited flying duties. Each of these studies had discussed flying phobia and its treatment with specific reference to the *acquisition* of such fear in persons whose occupation involved operational flying and which subsequently led to their avoidance of flying.

Denholz *et al* (1974, 1978) described an automated audio-visual programme which combined desensitisation, modelling and positive reinforcement, so allowing 40 out of 51 (78.4%) civilian participants, who undertook the programme, to fly. Twenty-six of those who had flown after treatment were contacted three and a half years later. Twenty-three of them had maintained their ability to fly.

Solyom *et al* (1973), in a study of treatment efficacy for 40 patients with air travel phobia, used three behaviour therapy techniques – aversion relief, systematic desensitisation, and habituation – all of which proved equally effective in significantly reducing the phobia, while group psychotherapy was ineffective. However, at follow-up, the difference between the approaches was no longer significant. The authors suggested that the behaviour therapy techniques achieved a more immediate result because they were more directly symptom-orientated. They also found that previous extensive flying experience tended to reduce the benefits of therapy.

In a study on 56 self-selected but screened civilian volunteers with a fear of flying, Howard *et al* (1983) compared results on small groups allocated to different regimes of therapy. After an eight-week programme of either systematic desensitisation, flooding, implosion, relaxation or no treatment, the subjects and therapists took a plane flight. Measures used during the flight failed to distinguish between the groups, a result which was attributed to the dilution of the comparative groups. We investigated a form of intervention on a larger number of subjects, which involved education, desensitisation and flooding.

Method

Participants

Participants were self-selected to the programme following national television and local radio coverage of a similar, apparently highly successful, course undertaken previously by two of us (JSMcC; NB) working with a local self-help group. In order to select *out* those with a simple apprehension, rather than a true fear of flying, entry requirements to the programme for evaluation were relatively strict. Each enquirer was sent information about the programme together with an enrolment form. All applicants were required to obtain in writing their doctor's certification that they were mentally and physically fit to attend the course. Forty-six people were recruited, 38 of whom completed the programme (11 males; 27 females). Their mean age was 44.3 years (s.d. 12.4 years).

Comparison group

Twelve people enquired about the programme too late to attend. They formed a comparison group (3 males; 9 females). Their mean age was 50.5 years (s.d. 10.6 years).

Programme

The principles of the intervention strategy included preparation by information, graded exposure over long sessions without avoidance, and group support with natural coping models. The course consisted of three sessions, each approximately three hours long, separated by one to two weeks.

The first session took the form of a group meeting at which talks were given by a psychologist on the physiology and behavioural control of fear; and by an experienced pilot on flight procedure and safety.

Session two was held at a nearby airport with the co-operation of its Director and British Midland Airways. It was designed to simulate all aspects of civilian flying without actually taking off. Participants were asked to check in and wait in the departure lounge until their 'flight' was called. During the waiting period help and support were given, where appropriate, by the course organisers although generally participants were encouraged to feel in control and to be personally coping. After being given an hour to become accustomed to the airport atmosphere, the group went through customary security checks and boarding procedures. On board, the passengers were seated, seat belts fastened, the aircraft doors closed, the steps removed and the engines started. Each procedure was explained carefully over the intercom by the pilot, and a simulated flight then took place. During this time standard announcements concerning altitude, weather, positional checks etc. were made. The atmosphere of realism was further reinforced by the serving of light refreshments by the cabin crew.

At the third session, smaller subgroups of between six and eight people undertook a scheduled return flight (courtesy of the airline) lasting approximately one hour each way. They were accompanied by two of the course organisers. During a 30-minute turn-around period participants remained on the aircraft. After disembarking, the course organisers reinforced the participants' coping strategies and emphasised the positive aspects of their experience.

Evaluation techniques

On enrolment in the programme, participants gave general demographic details of themselves and indicated whether they had flown previously, what worried them about flying and if they had ever received treatment for 'nervous tension'.

A series of 10 cm visual analogue scales was constructed. These were designed to monitor the severity of anxiety each participant felt they would experience in a number of situations connected with flying. The scales were completed before the first session, two days after finishing the course and at a one-year follow-up. The comparison group completed these scales one month apart, only.

All participants completed Spielberger's State Anxiety Inventory (SSAI) (Spielberger *et al*, 1970) during the introductory meeting and before boarding the aircraft at the second session. The SSAI was also completed on a further three occasions during the last session: one prior to boarding; one on board shortly prior to take-off and one mid-way through the return flight.

At follow-up, one year later, participants were asked whether they had flown during that period, and if so, how often. They were asked to comment on their experience and whether the programme had influenced their views about flying. At a three-year follow-up, participants were again contacted in order to identify a total number who had subsequently flown.

Results

Ill health, business pressures or the intervention of holidays prevented five people from completing the programme, three of whom did subsequently fly. A further three participants were too fearful to attempt the final session. This left a total of 38 people who completed all three sessions.

What worried people about flying?

Fourteen (37%) of the participants were worried about 'being enclosed'. That was the most common fear expressed. Thirteen people (34%) were afraid of crashing. Five people (13%) were frightened of heights. The remainder were fearful either of loss of control or air-sickness, or had multiple worries.

Anxiety profile across the programme

The median self-rated state anxiety scores are shown in Fig. 1. Analysis by the Wilcoxon matched-pairs test shows that there was no statistically significant difference between the scores obtained in the introductory session and those given before the simulated flight. Compared with initial levels, anxiety scores rose significantly before the actual flight ($P<0.001$) and, although falling significantly after take-off ($P<0.001$), remained higher during the outward flight ($P<0.01$) than at the initial meeting. On the return flight, however, anxiety levels fell markedly and were significantly less than they had been at the first meeting ($P<0.002$).

The Mann–Whitney U test identified less anxiety in the claustrophobic group in comparison with the group fearful

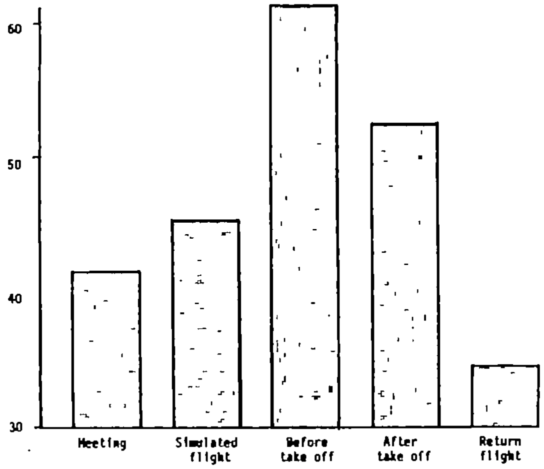

FIG. 1 Median Spielberger Anxiety Scores measured at points throughout the course.

of heights both after take-off ($P<0.05$) and on the return flight ($P<0.05$). The claustrophobic group, too, in comparison with those fearful of crashing, was less anxious after take-off ($P<0.05$) and on the return flight ($P=0.05$).

Scores on the visual analogue scales, completed two days after the programme, were compared with those obtained before the first meeting. After completing the course, participants felt less anxious about looking at photographs of aircraft ($P<0.04$), meeting people at an airport ($P<0.002$), watching a film of an aircraft taking off ($P<0.04$), waiting to board an aircraft ($P<0.001$), sitting in an aircraft ($P<0.001$), taking off ($P<0.001$), and flying over land ($P<0.001$) or water ($P<0.001$). They also rated aircraft as being less often in the news ($P<0.001$).

Comparisons were made of the analogue scores given by the untreated comparison group and those given by the course participants. The Mann–Whitney *U* test showed that the two groups did not differ initially on any scale, except one. The comparison group rated aircraft to be less often in the news than did the experimental group ($P<0.02$). After intervention and compared with the comparison group, the experimental group thought they would feel calmer when waiting in the departure lounge ($P<0.001$), boarding an aircraft ($P<0.001$), sitting in an aircraft ($P<0.001$), taking off ($P<0.001$), and flying over land ($P<0.001$) or water ($P<0.001$) (Fig. 2).

The mean anxiety scores of those who enrolled on the course but who were unable to complete it either because they were too fearful or because of ill-health, business or social reasons are shown in Table I. Small numbers preclude formal statistical analysis but it does appear that there is no marked difference in anxiety scores between those too fearful to undertake the final session, and those who either did undertake it, or for other reasons were unable to do so.

One-year follow-up

Thirty-six (95%) of the participants returned the follow-up questionnaire and analogue scales sent to them one year later. Compared with their preliminary completion of the scales, all subjects were significantly less anxious about all the aspects of flying covered by the questions. However, when compared with the scales completed immediately after the course, there was a significant rise in perceived anxiety associated with sitting in an aircraft ($P=0.001$), flying over land ($P=0.004$), and flying over water ($P=0.005$) (Fig. 3).

Two people did not return the questionnaires. One of them had previously communicated that she had undertaken a flight. Thus fifteen (39%) of the group had flown in the intervening year. Of the remainder, eleven people said they had not had the opportunity to fly; eight others had definite plans to do so and three more were too anxious to consider flying. One only was lost to follow-up. Thirty-two (84%)

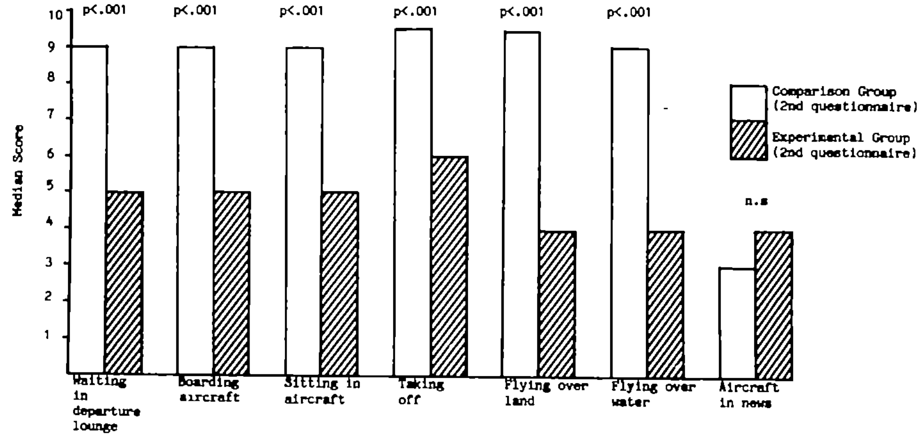

FIG. 2 Median score for fear of flying, visual analogue scale (after intervention): comparison group *v*. experimental group

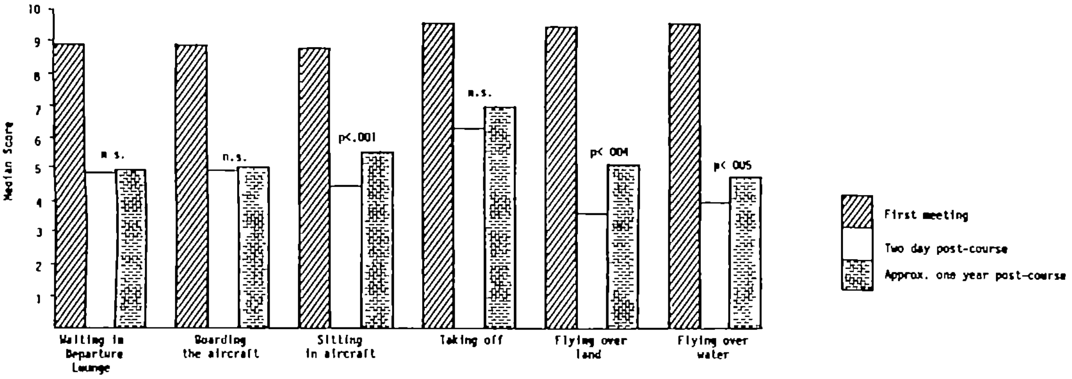

FIG. 3 Median score for fear of flying, visual analogue scale: the *P* values show the differences between the two-day post-course and the one-year post-course measurements

TABLE I
Mean SSAI scores for participants

	First meeting			*Simulated flight*		
	Mean	*s.d.*	*n*	*Mean*	*s.d.*	*n*
Subjects too fearful to complete the course	36.66	10.115	3	51.66	21.571	3
Subjects not completing the course for other reasons	45.00	13.416	5	46.75	0.957	4
Experimental subjects	43.44	14.157	36	46.37	12.661	37

of the participants reported themselves to be less anxious about flying.

The only variables to discriminate between those who had flown during the year and those who had not were those linked to changes in anxiety during the course. Participants who had flown after the course were those who had shown greatest reduction from the first session to the post-course evaluation in their rated anxiety while in the departure lounge ($P = 0.01$), boarding an aircraft ($P = 0.004$) and sitting in an aircraft ($P < 0.005$).

Three-year follow-up

Three years after the course, a total of 23 participants reported that they had flown (61%), ten had not flown (26%), and from five there was no reply to a questionnaire (13%).

Discussion

The aim of the course was simply stated as one of offering applicants the necessary degree of help and encouragement needed to enable them to travel by air. Since over 60% of the participants subsequently flew, it seemed that a fair degree of success could be claimed. However, since the subjects were self-selected, it is possible that they did not represent the most extreme cases of aerophobia. Nevertheless, two factors suggest that they did represent a group of people who were particularly fearful of flying. Firstly, nearly half the group had never flown before; and of those who had, the majority had not flown for many years. Secondly, there was the commitment needed to fulfil the requirements of the course. Participants had to obtain permission from their general practitioner and provide a certificate of fitness. Many had to travel substantial distances in winter weather conditions to attend the three long and stressful sessions. In short, they were a particular group but we thought them to be fairly typical of people with a moderate to severe fear of flying.

If subjective ratings are considered, the course also appears to have been successful. Although the confidence that was evident immediately after the course-flight had diminished slightly at the one-year follow-up, subjects did rate themselves as significantly less anxious about flying than they had been prior to the course. Of those who completed it, 84% claimed to be subsequently less anxious about flying. It was the apparent success of the course which made it difficult to assess which people had benefited most from it. It had been assumed that its educational element, together with the reassuring presence of an experienced pilot, would particularly benefit the inexperienced passenger and those who were anxious about crashing. This hypothesis was not, however, borne out by our findings. Similarly the claustrophobic group, who we feared would find the experience particularly stressful, was significantly less anxious during the flight than the rest of the group.

A secondary aim of the study was to attempt to identify those people who would benefit most from this form of treatment. In view of previous findings by Gelder *et al* (1973) that different types of phobias do not respond differently to flooding with the feared stimulus, it was perhaps not surprising that we failed to identify those who would do particularly well as a result of our intervention. The claustrophobic group was significantly less anxious than other groups during the course-flight but that was not reflected in their willingness to fly after the course.

Those who did subsequently fly were noted to have shown the greatest reduction from the first session to the post-course evaluation in their anxiety levels while in the departure lounge, boarding an aircraft and sitting in one.

From our results, it would seem unlikely that the personal characteristics of the phobic subject were important in determining the success of the treatment programme. The results, however, do seem to show that this form of group treatment, in civilian aerophobics, can be effective. Furthermore, in contrast to previous studies, which have involved numerous sessions, required specialised equipment and the time of psychologists skilled in behavioural therapy, our strategies were relatively economical (Solyom *et al*, 1973; Denholz & Mann, 1974; Denholz *et al*, 1978). Since we showed little evidence for an anxiolytic effect of giving phobics information about flying, it may be that more emphasis on exposure to the airport environment and aircraft and less emphasis on educational aspects might improve the therapeutic response and reduce the number of sessions needed.

Gelder *et al* (1973) have reported that prolonged exposure to the feared stimulus is as effective as systematic desensitisation in relieving phobias. Continuous exposure to the feared situation also seems more effective than continued brief ones (Stern & Marks, 1973), the latter of which may paradoxically increase fear (Stone & Borkovec, 1975). Our participants remained on the aircraft during the turn-around period in the third session, and that continuous exposure may have contributed to the marked fall in anxiety levels observed during the return flight.

Exposing phobics *in vivo* to the feared situation needs careful regulation: there are ethical problems in indiscriminately encouraging phobics, especially those with previous traumatic experiences of flying, to attempt air travel without appropriate psychological support. Nevertheless, with air travel becoming an increasingly routine activity, it does appear possible that airlines, co-operating with psychologists, could attempt some of the principles used in the present study in order to help some of their more fearful potential passengers to fly.

From Clinic to Community

CLOPIXOL®

zuclopenthixol dihydrochloride/decanoate

TABLETS • INJECTION • CONC INJECTION

PRESCRIBING INFORMATION

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.

Indications Psychoses.

Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses. Not recommended for children.

Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.

Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerence to other neuroleptics. Pregnancy (relative). Use with caution in patients with Parkinsonism, severe arteriosclerosis, senile confusional states; serious renal, hepatic or cardiovascular disease.

Overdosage Overdosage should be treated by gastric lavage.

Package Quantities and NHS Price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00.
PL Nos 0458/0027,0028,0029. PA Nos 115/5/3,4,6.

CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.

Indications Psychoses, especially schizophrenia.

Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.
Not recommended for children.

Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.

Contraindications Comatose states.

Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.

Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur. (b) By sedation (with benzodiazepines) in the unlikely event of agitation or excitement. (c) By noradrenaline in saline intravenous drip if the patient is shocked.

Package Quantities & NHS Price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23.
PL Nos 0458/0017,0041. PA Nos 115/5/1,5,7

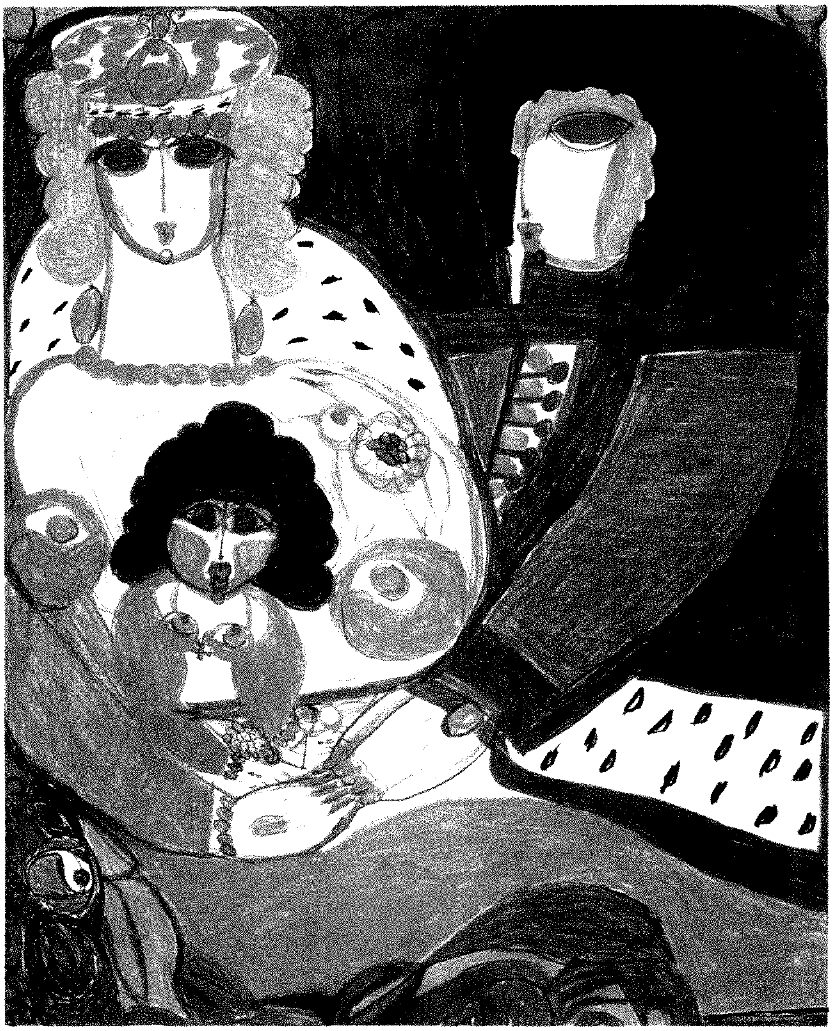
AN EXPRESSION OF SCHIZOPHRENIA.

Aloise was diagnosed as schizophrenic at the Cery Asylum, Lausanne. She was later transferred to the Asylum de la Rosiere where she remained for over 40 years until her death in 1964.

During the last 20 years of her life she worked steadily at her drawings.

The illustration below is produced with kind permission of the Musee Cantonal Beaux-Arts, Lausanne.



A TREATMENT.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol, it has become widely established throughout the world as an effective anti-psychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration of action following a single deep intramuscular injection.

In mild symptomatology the dosage for Haldol* Decanoate is from 50-100mg given 4-weekly, whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation[1] and a reduced requirement for antiparkinsonian medication[2] leaving him/her better able to participate in other forms of therapy.

100mg/ml

HALDOL*

haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

Presentation: Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses**: As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side effects, precautions, contra-indications**: Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side effects: In common with all neuroleptics, the following side effects may be observed, sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Occasional local reactions such as erythema, swelling or tender lumps have been reported. In common with other anti psychotics, haloperidol has been associated with rare cases of neuroleptic malignant syndrome. **Dosage**: Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. An initial dose of 50mg every 4 weeks is recommended increasing if necessary after 2 weeks by 50mg increments to 300mg every 4 weeks. The dosage should be tailored to suit the individual patient and to reflect previous oral dosage. In adults 100mg Haldol* Decanoate is approximately equal to 500mg chlorpromazine (or equivalent) per day. Caution is required with the elderly, starting doses of 12.5mg to 50mg monthly should be tried first. **Product Licence Numbers**: 0242/0095, 0242/0094 **Basic NHS Cost**: 1ml x 100mg/ml x 5 £24.00 1ml x 50mg/ml x 5 £15.60. (Correct at time of printing). Further information is available on request from: **Janssen Pharmaceutical Limited.** Grove, Wantage, Oxon OX12 0DQ.

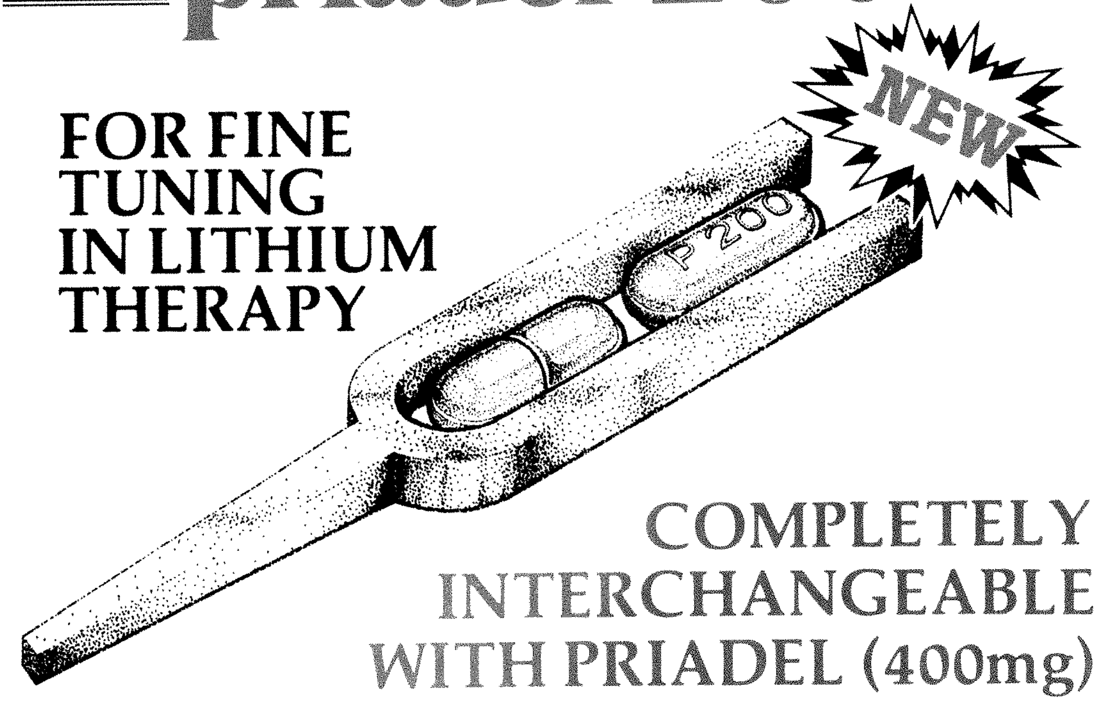
PHARMACEUTICAL LTD

priadel® 200



FOR FINE TUNING IN LITHIUM THERAPY

COMPLETELY INTERCHANGEABLE WITH PRIADEL (400mg) WITHOUT RE-STABILISATION

priadel® — the world's first controlled release lithium now offers maximum flexibility of dosage

---

PRESCRIBING INFORMATION

Presentation
Each Priadel 200 Tablet contains 200mg lithium carbonate Ph.Eur. in a controlled release formulation. Also Priadel Tablets each containing 400mg lithium carbonate in the same controlled release formulation.

Indications
Treatment and prophylaxis of all elements of affective illness. For the control of aggressive or self-mutilating behaviour.

Dosage
In patients of average weight (70kg) 400—1200mg daily as a single dose, usually on retiring. Check serum lithium level at least 12 hours after the last dose on day 4 or 5. The twelve-hour serum level should be in the range 0.7—1.0 mmol/l. Adjust dose where necessary and check serum lithium level weekly until stabilisation has been achieved.

Contra-indications, warnings etc.
Renal and cardiovascular insufficiency. Addison's disease and untreated hypothyroidism. Recommendation to discontinue Priadel before planned pregnancy and for the first trimester. Exercise care in circumstances where electrolyte balance may be disturbed due to concurrent infections or other medication, for example diuretics, appetite suppressants and steroids. See Data Sheet for reported possible drug interactions.

Side effects and precautions
Initiation of lithium therapy may give rise to transient side effects which usually disappear following stabilisation. These include fine hand tremor, weight gain, polydipsia, polyuria and anorexia. Nausea and diarrhoea which are related to the site and rate of absorption are minimised by the controlled release formulation of Priadel. Long-term treatment with lithium may be associated with disturbances of thyroid or renal function which should be monitored.

Toxic effects which may be indicative of impending lithium intoxication include: increasing anorexia, diarrhoea, vomiting, muscle weakness, lack of co-ordination, drowsiness or lethargy progressing to giddiness with ataxia, tinnitus, blurred vision, dysarthria, seizures and coma.

Winter-Born *v* Summer-Born Schizophrenics

R. E. KENDELL and I. W. KEMP

Data from two sources – the Edinburgh Psychiatric Case Register and the psychiatric in-patient records of the Scottish Health Service – were used to compare large populations of first-admission schizophrenics born in winter (January to March) and in summer (June to October). Parallel comparisons were carried out for affective psychoses. Comparison of the months of birth of the Scottish patients with those of the general population indicated that there was a 9% excess of schizophrenic births and a 3% excess of affective births in the first 3 months of the year. In the Edinburgh material, winter-born schizophrenics were more likely than the summer-born to receive a diagnosis of paranoid or schizoaffective schizophrenia and less likely to receive diagnoses other than schizophrenia on readmission, but neither of these differences emerged in the much larger Scottish material. There were no differences between winter- and summer-born schizophrenics in age of onset, sex ratio, or prognosis in either data set, nor were any significant differences found between winter- and summer-born affectives. We have therefore failed to demonstrate any convincing differences between winter- and summer-born schizophrenics.

In many countries in the temperate latitudes of the northern hemisphere, schizophrenics are born in the winter months more often than other people. In Sweden (Dalen, 1968), Denmark (Videbech *et al*, 1974), Norway (Ødegaard, 1974), England and Wales (Hare *et al*, 1974) and the United States (Torrey *et al*, 1977), large representative populations of schizophrenics have been compared with general population controls closely matched for year and place of birth. In all of these countries a modest but statistically significant excess of schizophrenic births was found in the winter months, particularly January, February and March. Similar well controlled studies have not yet been carried out in the southern hemisphere, but the indications are that there is a similar excess of winter births (i.e. in July to September) in South Africa (Dalen, 1975) and Australia (Parker & Neilson, 1976; Jones & Frei, 1979). Although Hare *et al* (1974) found an excess of winter births in manic–depressives as well, most investigators have found this season-of-birth effect only in schizophrenics. It also seems likely that the birth dates of the siblings of schizophrenics do not differ from those of the general population (Buck & Simpson, 1978), although the evidence on this score is conflicting (Hare, 1976). This all suggests that some environmental influence acting *in utero* or in the early months of life and varying with the season of year is contributing to the aetiology of at least some forms of schizophrenia. A viral infection is one of many possibilities, and receives some support from the finding that the excess of schizophrenic births is greater in years with particularly cold winters (Hare & Moran, 1981).

If some agent making an important contribution to the aetiology of schizophrenia acts only, or mainly, in the winter months, there might be differences between the schizophrenic illnesses to which this seasonal agent had and had not contributed. If so, there might be detectable differences between summer-born and winter-born schizophrenics – in age of onset, perhaps, or in symptoms, treatment response or prognosis. However, even if one assumes that this seasonal agent acts only in the three winter months January to March, and that it makes a major contribution to aetiology, the fact that the observed excess of winter births was only about 8% in most of the studies referred to above implies that, even in these winter months, this seasonal agent is either making no contribution at all to the aetiology of over 90% of future schizophrenic illnesses or, if it is making a contribution, no more than it does at other times of the year. This means that very large populations of summer- and winter-born schizophrenics would have to be compared before significant differences between the two could be expected to emerge, even if illnesses to whose aetiology the seasonal agent had contributed were appreciably different in some respect from other schizophrenic illnesses. However, Dalen (1975) and Pulver *et al* (1983) have both reported that the excess of winter births is greater in, or restricted to, schizophrenics with a relatively good prognosis, and Watson *et al* (1984) have reported that it may be greater in unmarried schizophrenics, which suggests that there may be important differences to be found.

This study reports two attempts, one based on 571 schizophrenics from the Edinburgh Psychiatric Case Register, the other on 2653 schizophrenics from the whole of Scotland, to detect differences between those born in winter and summer months.

Method

Edinburgh Psychiatric Case Register (EPCR) data

The EPCR covers the 470 000 inhabitants of the city of Edinburgh and has recorded data on all psychiatric admissions since 1 January 1970 and on all psychiatric contacts, as in-patient or general hospital ward referral, since 1 January 1978. Information was extracted from the register files in March 1983 on all first-admission schizophrenics (i.e. first admissions to the EPCR since 1 January 1970, including the resident population of the Royal Edinburgh Hospital on that date, with a discharge diagnosis of ICD 295) who were aged 15–39 inclusive at the time of admission and whose date of birth was known.

The 222 schizophrenics fulfilling these criteria with a birth date between 1 January and 31 March were then compared with the 349 born between 1 June and 31 October on the 13 variables listed in Table I. An analogous comparison was also carried out for affective psychosis first admissions; that is, between the 198 first admissions aged 15–39 with a discharge diagnosis of affective psychosis (ICD 296) who were born in January to March and the 277 born in June to October. The reason for this parallel comparison of first-admission affective psychotics was to check that any difference found between winter- and summer-born schizophrenics was specific to schizophrenia.

The reason for comparing the 3-month period January to March with the 5-month period June to October was more complicated. Scotland happens to be one of the few countries in north-west Europe in which the birth dates of schizophrenics have not been compared with those of the population as a whole, so the months with an excess of schizophrenic births are unknown. In England and Wales and most northern-hemisphere countries these are, in most years, January to March, but in Norway the excess extends from January to May (Ødegaard, 1974), in Eire the excess is in the second quarter of the year (O'Hare *et al*, 1980) and in the United States it extends from December to May (Torrey *et al*, 1977). Omitting patients born in November, December, April, and May therefore minimises the chances of the summer-born population being contaminated with patients who actually represent part of the winter peak.

TABLE I

EPCR items on which winter- and summer-born patients were compared

1. Age on admission
2. Sex
3. Marital status
4. Admission status (formal or informal)
5. Place of birth
6. Social class
7. Employment status before admission
8. Living group before admission
9. Duration of initial admission
10. Number of readmissions 1970–1982
11. Cumulative duration of all admissions 1970–1982
12. Discharge diagnosis (initial admission)
13. Discharge diagnosis (all readmissions)

There was no significant difference between winter- and summer-born schizophrenics on any of the first eleven items listed in Table I (see Table II). There was, however, a significant ($\chi^2=14.6$ and $P=0.044$) difference in the distribution of the original discharge diagnoses of the two, more of the winter-born patients having a diagnosis of paranoid or schizoaffective schizophrenia and more of the summer-born patients a diagnosis of latent schizophrenia or acute schizophrenic episode (Table III). The distributions of their readmission diagnoses were also very different (Table IV), with a far higher proportion of the readmission diagnoses of the summer-born patients being diagnoses other than schizophrenia (33% *v.* 15%). Comparison of these two distributions using the chi-squared test suggests that they are dramatically different ($\chi^2=38.5$ and $P<0.0001$ with 2 d.f.), but this very low chance probability is misleading, for some patients were readmitted more often than others and so had a greater influence on the overall distribution of readmission diagnoses. In fact, the striking difference obtained is largely due to the fact that, by chance, a small number of summer-born schizophrenics were readmitted with diagnoses other than schizophrenia a very large number of times. When the distributions of the different patterns of readmission diagnoses observed in individual patients were compared in the summer-born and the winter-born (i.e. counting each patient once only), the difference between the two was much less striking ($\chi^2=6.31$ and $P=0.043$). However, there is still a significant difference between the readmission diagnoses of summer- and winter-born schizophrenics, as there was for their first-admission diagnoses. There was no significant difference between winter- and summer-born affectives on any of the 13 items. In particular, there was no difference in the distributions of either their initial or their readmission diagnoses.

Scottish national data

Since 1963, information has been collected on all admissions to and discharges from all psychiatric hospitals and units in Scotland by the Common Services Agency of the Scottish Health Service. This information (SMR4) is less extensive than that recorded by the EPCR but covers a population ten times as large – the 5 200 000 inhabitants of Scotland. Comparisons between winter- and summer-born schizophrenics and winter- and summer-born affectives were carried out in exactly the same way as with the EPCR patients. That is, both comparisons were restricted to patients aged 15–39 inclusive at the time of admission, with known date of birth and with no known previous in-patient psychiatric care; schizophrenia was defined as a discharge

TABLE II
Comparisons between winter- and summer-born Edinburgh patients

	Schizophrenics		*Affectives*	
	Winter-born	*Summer-born*	*Winter-born*	*Summer-born*
Number of patients	222	349	198	277
Mean age on first admission	27.9	27.5	29.5	29.4
Sex (% male)	60.8	62.8	44.4	40.8
Marital status				
Never married (%)	76.6	74.8	45.5	41.9
Married (%)	14.9	19.2	46.0	46.6
Other (%)	8.6	6.0	8.6	11.6
Admission status (% informal)	81.1	78.8	85.9	89.2
Duration of first admission (weeks)				
Median	5.9	8.3	5.0	5.2
Mean	151.1	146.4	7.4	16.9
Number of readmissions				
Median	0.0	1.0	0.0	0.0
Mean	1.5	1.8	1.1	0.9
Cumulative duration of all admissions (weeks)				
Median	12.0	16.4	8.1	8.1
Mean	179.7	168.1	13.8	24.0

Notes. None of the differences between winter- and summer-born patients is statistically significant. For age, student's t test was used. For duration of first admission, number of readmissions and cumulative duration of all admissions, the non-parametric Kolmogorov-Smirnov Two Sample Test was used because of their skewed distributions. For all other variables the χ^2 test was used.

The great disparity between the median and mean durations of schizophrenic admissions is due to a small number of patients whose first admission had lasted for up to 30 years.

TABLE III
Discharge diagnoses of winter- and summer-born Edinburgh patients: first admissions

Schizophrenics[1]	*Winter-born (n = 222)*	*Summer-born (n = 349)*
Simple (%)	7.7	5.7
Hebephrenic (%)	6.3	7.7

Other (%)	8.6	10.1
Unspecified (%)	4.5	2.9

1. $\chi^2 = 14.6$ and $P = 0.044$ with 7 d.f.
2. $\chi^2 = 3.79$ and $P = 0.4$ with 4 d.f.

Note. The number of diagnostic categories shown in Tables III, IV, VI and VII do not always correspond with the number of degrees of freedom shown in the χ^2 comparisons. This is because some diagnostic categories have been combined for ease of presentation.

diagnosis of ICD 295 and affective psychosis as a discharge diagnosis of ICD 296; and winter-born was defined as having a birth date in January to March and summer-born as having a birth date in June to October.

The comparisons were based on SMR4 data for the 12-year period 1970–1981 and involved ten of the 13 items listed in Table I (all except 5, 6 and 8). Comparison of the number of readmissions, the cumulative duration of all admissions (first admissions and readmissions combined) and the discharge diagnoses of readmissions was more difficult than it had been for the Edinburgh patients because, unlike the EPCR returns, the SMR4 returns for the successive admissions of a single individual are not normally linked together. A special linkage exercise therefore had to be mounted using surname, date of birth, sex and the hospital's case reference number as identifying data. By this means almost all readmissions to the hospital to which the patient was originally admitted would have been identified. The majority of admissions to other psychiatric hospitals or units in Scotland should also have been identified, though women whose surname changed in the interim, and men or women whose surname was misspelt or whose date of birth was wrongly recorded might well have been missed. Admissions to hospitals in other parts of the United Kingdom would, of course, also have been missed. In order to restrict to manageable numbers the total number of SMR4 returns needing to be scanned, only admissions with a discharge diagnosis of schizophrenia (ICD 295) or affective psychosis (ICD 296) were included in the linkage exercise. As a result, readmissions with other diagnoses, which in the EPCR pilot study had amounted

Schizophrenia (%)	6.6	6.0
All other diagnoses (%)	20.7	23.8

1. $\chi^2 = 6.31$ and $P = 0.043$ with 2 d.f.
2. $\chi^2 = 7.51$ and $P = 0.11$ with 4 d.f.

to 14% of all the schizophrenics' readmissions, were not identified.

Results

The results are shown in Tables V to VII. None of the comparisons set out in these three tables involves a difference between summer- and winter-born patients which is statistically significant even at the 10% level. In particular, there is no significant difference between the first-admission diagnoses of winter- and summer-born schizophrenics. The proportion of patients with a diagnosis of paranoid or schizo-affective schizophrenia is marginally higher in the winter-born (23.% *v.* 21.5%), but even this modest difference is entirely due to the 274 Royal Edinburgh Hospital patients in the Scottish sample. When the comparison was repeated after removing these 274 patients (10.3% of the total), the diagnoses of winter- and summer-born patients were virtually identical ($\chi^2 = 4.01$ and $P = 0.91$ with 9 d.f.). There is no significant difference between the readmission diagnoses of summer- and winter-born schizophrenics either. So again the findings of the EPCR study are not confirmed. However, when Royal Edinburgh Hospital and other Scottish patients were examined separately, there was a striking tendency in the former for a higher proportion of the readmissions of summer-born than of winter-born patients to be given a diagnosis of affective psychosis (19% *v.* 5%). So this does at least confirm that the EPCR finding described above was not generated by a programming error.

Although the season-of-birth effect has never been studied in Scottish schizophrenics, its existence can be demonstrated and its approximate magnitude calculated from these data. For schizophrenia the 90.25 days between 1 January and 31 March produced 1057 first admissions,

TABLE V

Comparisons between winter- and summer-born Scottish patients

	Schizophrenics		*Affectives*	
	Winter-born	*Summer-born*	*Winter-born*	*Summer-born*
Number of patients	1057	1596	933	1487
Mean age at first admission	26.3	26.2	29.3	29.2
Sex (% male)	62.1	59.5	32.6	34.9
Marital status				
Never married (%)	68.4	67.6	32.0	34.0
Married (%)	25.0	26.4	60.9	58.6
Other (%)	6.6	6.0	7.1	7.5
Admission status (% informal)	77.8	77.1	87.8	89.4
Duration of first admission (weeks)				
Median	5.9	5.7	4.1	4.1
Mean	10.3	10.4	6.1	6.1
Number of readmissions				
Median	0.0	1.0	0.0	0.0
Mean	1.4	1.4	0.7	0.7
Cumulative duration of all admissions (weeks)				
Median	10.9	10.6	6.0	5.6
Mean	29.6	31.9	13.0	12.3

Notes. None of the differences between winter- and summer-born patients is statistically significant. For sex and for marital, admission and employment status the χ^2 test was used. The Kolmogorov-Smirnov Two Sample Test was used for age, duration of first admission, number of readmissions and cumulative duration of all admissions, because of their skewed distributions.

manic–depressive manic (%)	23.4	23.1
manic–depressive depressed (%)	36.8	37.7
other (%)	9.6	10.2
unspecified (%)	11.5	11.4
Schizophrenia (%)	18.7	17.6

1. $\chi^2 = 0.05$ and $P = 0.98$ with 2 d.f.
2. $\chi^2 0.49$ and $P = 0.97$ with 4 d.f.
3. These totals do not include the 76 readmissions still in hospital on 31 December 1981, nor do they include any readmissions with diagnoses other than schizophrenia or affective psychosis.

while the 153 days between 1 June and 31 October produced 1596. The admission rate of winter-born relative to that of summer-born patients is therefore

$$\left(\frac{1057}{90.25}\right) + \left(\frac{1596}{153}\right) = 1.1228$$

For affectives the 90.25 days in January to March produced 933 first admissions while the 153 days in June to October produced 1487. The admission rate of the winter-born relative to the summer-born is therefore

$$\left(\frac{933}{90.25}\right) \div \left(\frac{1487}{153}\right) = 1.0637$$

Patients admitted to hospital in the 12-year period 1970–1981 who were 15–39 at the time of admission would have been born after 1929 and before 1967. Since 1931, the annual reports of the Registrar General for Scotland have given tables of the number of births registered each month, and it is apparent from these that for most of the 37 years between 1930 and 1966 the birth rate was higher in January to March than in June to October. Taking the 3 years 1940, 1950 and 1960 as a sample of that 37-year period (and remembering that 1940 and 1960 were leap years), it was calculated from these tables that the ratio of the Scottish birth rate in January to March to that in June to October was 1.033. The excess admission rate of winter-born schizophrenics relative to the summer-born is therefore

$$\left[\left(\frac{1.1228}{1.033}\right) - 1\right] \times 100 = 8.7\%$$

and the excess admission rate of winter-born affectives relative to the summer-born is

$$\left[\left(\frac{1.0637}{1.033}\right) - 1\right] \times 100 = 3.0\%$$

Discussion

The comparison of the months of birth of Scottish patients and those of the general Scottish population carried out here suggests that there is a 9% excess of schizophrenic births and a 3% excess of affective psychosis births in the first 3 months of the year. The season-of-birth effect is therefore demonstrable in Scotland, as in England and Wales and most other countries in the temperate latitudes of the northern hemisphere. The main purpose of the study, however, was to detect differences between winter- and summer-born patients rather than to demonstrate yet again an excess of winter-born schizophrenics.

The ratings used to compare winter- and summer-born patients were routine statistical returns with the familiar shortcomings of such data. They were of unknown reliability, sometimes incomplete, and the diagnoses they incorporated were made, often by junior medical staff, to unspecified and almost certainly varying criteria. However, all these sources of low reliability and bias should affect winter- and summer-born patients to the same extent. The deficiencies might obscure genuine differences, but it is difficult to see how they could generate spurious differences between groups of patients born at different times of the year.

Although winter- and summer-born patients were compared on several different variables, no statistically significant differences were found between winter- and summer-born affectives, and the only significant differences between winter- and summer-born schizophrenics were differences in the distributions of both first-admission and readmission diagnoses in the Edinburgh patients. These diagnostic differences were only significant at the 5% level; they were not accompanied by any difference in age of onset, readmission rate or total duration of hospitalisation; nor are they easily reconciled with one another. Moreover, no analogous differences were found in the second study based on patients drawn from the whole of Scotland, despite the considerably larger numbers of patients available (there were 1057 winter-born Scottish schizophrenics, compared with 222 in the EPCR study). It seems likely, therefore, that these diagnostic differences were generated by chance. It is true that in the Scottish study diagnoses other than schizophrenia or affective psychosis were not identified by the linkage program used to detect readmissions, and that if they had been a significant difference in the range of readmission diagnoses might have emerged. But the major component of the difference between summer- and winter-born patients in the EPCR comparison had been in the proportion of diagnoses changed to affective psychosis, and there was no hint of any difference in this respect in the Scottish material.

Dalen (1975) and Pulver *et al* (1983) have reported previously that the excess of winter births is greater in, or restricted to, schizophrenics with a relatively good prognosis. However, there is no evidence here, in either the EPCR or the Scottish material, that winter-born patients have a better prognosis than the summer-born. The duration of the original admission, the number of readmissions and the cumulative duration of all admissions of winter- and summer-born patients are all indistinguishable. For all three variables, Kolmogorov–Smirnov tests failed to reveal a difference significant even at the 10% level. It is true that, on average, our patients were only followed for a period of 5–6 years after their original admission, and that significant differences might have emerged if the observation period had been longer. Even so, the combination of these three variables ought to provide a fairly sensitive index of prognosis, certainly more sensitive than those used by Dalen (1975) and Pulver *et al* (1983), who both relied entirely on the duration of the original admission, and in the Scottish study at least patient numbers were substantial. Nor do our data provide any support for the suggestion of Watson *et al* (1984) that the season-of-birth effect predominates in unmarried schizophrenics.

We conclude, therefore, that we have failed to demonstrate any convincing difference between winter- and summer-born schizophrenics, or even to find any strong suggestions that such differences are there to be found. But for a variety of reasons this does not necessarily mean that there are none. In particular, it is important that the possibility, raised by the findings of Kinney & Jacobsen (1978) and Shur (1982), that there is no excess of winter births in schizophrenics with a positive family history should be investigated further.

P300 and CT Scan in Patients with Chronic Schizophrenia

A. ROMANI, S. MERELLO, L. GOZZOLI, F. ZERBI, M. GRASSI and V. COSI

Twenty chronic male schizophrenic subjects aged 30–50 years were examined by an auditory event-related potential procedure for the evaluation of the P300 component, a CT scan and a neuropsychological test battery. The P300 latency was increased and its amplitude was reduced. CT scan measures showed lateral and third ventricle enlargement, and there was a global neuropsychological impairment. Poor neuropsychological performances were consistently associated with delayed P300 latencies, but not with CT scan measures. Ventricular enlargement was more pronounced among subjects with a negative family history for major psychiatric disorders.

There is consistent evidence (Heaton *et al*, 1978) that chronic schizophrenic subjects perform poorly on neuropsychological tests. Whether there may be specific patterns linked to a deteriorating course and affecting all diagnostic subgroups remains unclear, although some authors have suggested that characteristic features are present (De Wolfe *et al*, 1971; Davis *et al*, 1972; Liddle & Crow, 1984), and others have even proposed anatomo-functional models which could explain the spectrum of the 'negative' symptomatology (Levin, 1984). It has been long suspected that schizophrenic cognitive impairment may not have an exclusively 'functional' origin. 'Soft' neurological signs have been repeatedly described in this condition (Rochford *et al*, 1970), as well as histopathological (Fisman, 1975), pneumoencephalographic (Haug, 1962), electroencephalographic (EEG) (Itil *et al*, 1972) and more recently, computerised tomographic (CT) scan (Johnstone *et al*, 1976) and regional cerebral blood flow (Ariel *et al*, 1983) abnormalities.

Brain morphology as investigated with CT scan has been the subject of many studies, which have given inconclusive results regarding the localisation of abnormal findings: enlargement of lateral ventricles (Andreasen *et al*, 1982*b*; Owens *et al*, 1985), third ventricle enlargement (Tanaka *et al*, 1981), fourth ventricle enlargement (Lippman *et al*, 1982) and the association of structural abnormalities with clinical variables (Andreasen *et al*, 1982*a*; Nasrallah *et al*, 1982; Rieder *et al*, 1983). Some authors have reported normal findings (Jernigan *et al*, 1982; Benes *et al*, 1982).

Another approach to the problem of cognitive deficit in schizophrenia has been advanced by some authors (Baribeau-Braun *et al*, 1983; Pfefferbaum *et al*, 1984), who studied the late positive component of event-related potentials (ERPs) – P3 or P300 – and described an increase in latency in schizophrenics, which is thought to be a characteristic of demented patients (Goodin *et al*, 1978; Leppler *et al*, 1984).

In the present study a multimodal approach has been used to investigate possible relationships between schizophrenic deterioration and clinical, neuropsychological, neuroradiological and neurophysiological parameters.

Method

Subjects

Twenty male subjects were selected among the long-stay patients (at least 5 years' hospitalisation) of San Colombano al Lambro Fatebenefratelli Psychiatric Hospital according to the following criteria.

The first criterion was diagnosis of 'schizophrenic disorder – chronic course' according to DSM-III criteria (American Psychiatric Association, 1980). Five subjects were classified as 'paranoid type', four as 'disorganised type' and eleven as 'residual type'. Eight subjects had a positive family history (first-degree relatives) for schizophrenia (six) or major depression requiring hospitalisation (two). They were evenly distributed among diagnostic subtypes.

The second inclusion criterion was monotherapy with haloperidol 4–6 mg/day p.o. for at least 6 months preceding the investigation. The third criterion was absence of other psychiatric or neurological diseases.

The fourth criterion was ability to co-operate with the test procedures. A preliminary study showed that most chronic schizophrenics with a memory quotient (MQ) score of 70 or less on the Wechsler Memory Scale were not able to perform the counting task of the ERP paradigms. An MQ score of at least 75 was therefore established as an inclusion criterion.

The patients were aged between 30 and 50 years (mean, 42 years); they had had 5–8 years of education.

Control groups

It was not possible to perform the ERP procedures, the neuropsychological tests and the CT scan on a single control group. Therefore two control groups, each of 20 age-matched male subjects, were selected. The first group consisted of healthy volunteers who were submitted to the ERP procedures and to the neuropsychological test battery. The educational status of this group (6–8 years education) was similar to that of the patients. The second group consisted of hospitalised patients diagnosed as having chronic tension headache (six), migraine (eight), Bell's palsy (three) or neuroses (three). CT scans were performed on the second group.

Procedure

The patients were submitted to the ERP procedures in the late hours of the morning. Within 7 days they were tested with the neuropsychological battery, and within a period of 6 months, 18 of them received a CT scan. One patient did not give his informed consent for the CT scan, and the other died because of pneumonia.

Event-related potentials

The ERP procedure took place in a sound-attenuated, electrically shielded cabin. Surface electrodes were placed as follows:

Channel 1: vertex – linked earlobes
Channel 2: internal chantus – infraorbital region (eye movement and blink contaminated trials were automatically excluded)
Fpz was grounded.

The EEG was processed by an OTE 1239 Neuroaverager (512 words; band width 0.5 – 50 Hz; time base 500 ms; bin width 0.98 ms). The stimuli (800 Hz tone bursts; duration 30 ms; rise/fall time 10 ms) were delivered by an Alvar Pluristim IV stimulator through two small loudspeakers placed 20 cm away on the right and left of the subject's head.

The auditory ERP procedure included the following four paradigms, three of which (2–4) required selective attention. In paradigm 1 the subject was instructed to count binaurally presented tones. Stimulus intensity was 70 dB SL and inter-stimulus interval (ISI) was 2 s; 20 stimuli were presented.

In paradigm 2 the subject was instructed to count only the stimuli presented to the right ear. In this paradigm 22 (rare) tones presented to the right ear alternated in a pseudo-random order with 110 (frequent) tones presented to the left ear. Stimulus intensity was 70 dB SL and ISI was 2 s.

Paradigm 3 was specular to paradigm 2: the subject had to count only the rare stimuli presented to the left ear.

In paradigm 4, the subject was instructed to count only the 'loud' stimuli. In this paradigm 22 binaural (rare) tones with an intensity of 70 dB SL alternated in a pseudo-random order with 110 (frequent) tones of 50 dB SL. ISI was 2 s.

In paradigm 1, responses to all stimuli were averaged, while in paradigms 2–4, only responses to rare stimuli were averaged.

The averaged signals were plotted by means of a Phillips 8040 X–Y recorder.

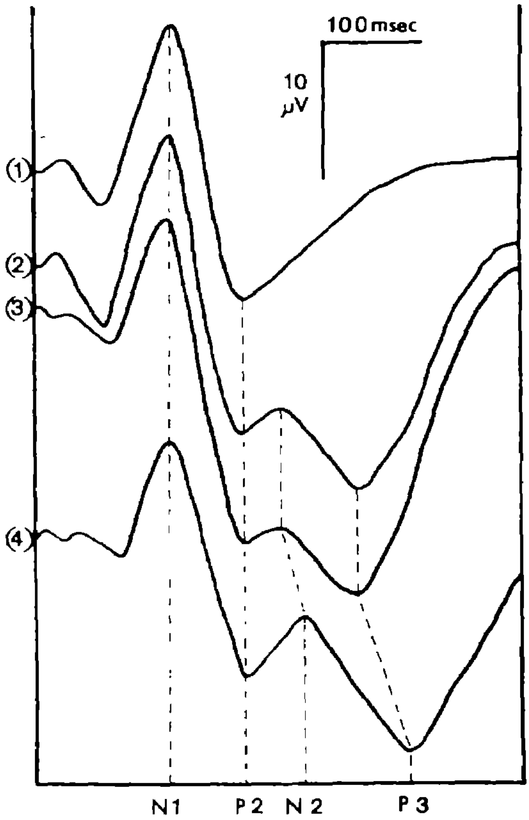

FIG. 1 Example of event-related potentials obtained in paradigms 1–4 in a control subject. The dashed lines identify the peaks N1, P2, N2 and P3. Negativity upwards.

Peaks were visually identified by adopting the following criteria: N1 was the first large negative peak falling in the interval 75–150 ms; P2 was the subsequent positive peak falling in the interval 150–250 ms. These two peaks were evident in all paradigms (Fig. 1). In selective-attention paradigms two further negative–positive waves, usually labelled N2 and P3 (or P300), appeared (see traces 2–4 of Fig. 1). P3 latency fell in the interval 320–480 ms, and N2 was the greatest negative peak between P2 and P3. Latency values of peaks N1, P2, N2 and P3, as well as peak-to-peak amplitudes N1–P2, P2–N2, N2–P3 and N1–P3, were considered for data analysis.

Neuropsychological battery

The following psychological tests were used: Wechsler Memory Scale, form I (WMS); Wechsler Bellevue I (WB); Raven Progressive Matrices '38 (PM 38); and the Toulouse-Pieron (TP). The TP is a test of attention in which the subject is presented with a large grid of eight similar geometric figures and asked to indicate all occurrences of four particular figures by drawing lines through them. Only quantitative performance has been analysed, according to Hiltmann (1960).

The analysis of data was performed on raw scores of single items and on age-corrected indices.

CT scan

In the CT scan, slices of 10 mm were performed from base to vertex (scanner EMI 1010). The following dimensions were measured: (a) the distance between the most lateral portions of the frontal horns; (b) the width of the lateral ventricles at the level of the caudate nuclei; (c) the dimensions of the four largest cortical sulci visible in the three upper slices; (d) the width of the third ventricle at the level of Monroe's foramina.

As described by Huckman *et al* (1975), the two ventricular dimensions were added and a single measure of ventricular size (V-index) was derived; the sum of measures of the four largest sulci supplied the degree of cortical atrophy (C-index).

Neurophysiological and neuroradiological measures were scored independently by two of the authors (A.R. and L.G. respectively), blind to the identities and diagnostic categories; neuropsychological tests were performed by one of the authors (S.M.), who was unaware of the results obtained by CT scan and EEG.

Statistical analysis

Statistical analysis was performed by comparing mean values of independent samples (Student's t test), by calculating Pearson's (r) and Spearman's (r_s) correlation coefficients and by linear regression analysis. A principal component analysis (PCA) (Lebart *et al*, 1977) was performed on Spearman's coefficients obtained from correlations of neuropsychological scores, and the main factors that were derived were entered as independent variables in multiple regression analysis.

Results

ERPs

Both in control subjects and in schizophrenic patients, well defined N1-P2 shaped potentials were obtained in paradigm 1, and N1-P2-N2-P3 shaped potentials were obtained in paradigms 2–4 (Fig. 1). In some cases N2 was recognisable only as a step on a large N1-P3 wave. In these cases P2-N2 amplitude was zero.

Mean latency and amplitude values are reported in Table I. A highly significant latency increase was observed only for peak P300, but it was also evident for N2. Latencies of N1 and P2 did not differ between schizophrenics and controls.

TABLE I

Mean values of peak latencies and peak-to-peak amplitudes of schizophrenic (S) and control (C) subjects

Peak	*Subjects*	*Latencies (ms)* *Paradigm 1*	*Paradigm 2*	*Paradigm 3*	*Paradigm 4*
N1	C	112	122	120	121

*$P<0.05$; **$P<0.01$; ***$P<0.001$.

The most consistent ($P<0.001$) amplitude reductions in schizophrenics were found for N1-P3, but N1-P2 amplitude was also reduced in the selective-attention paradigms (2–4), as well as in the simple counting paradigm (1). P2-N2 and N2-P3 amplitudes did not differ significantly. This may be at least partially attributed to a greater relative variation. The coefficients of variation (CV) of these two amplitudes had values ranging from 45% to 75%, whereas for N1-P2 and N1-P3 the CV values ranged from 25% to 40%. This greater variability of N2-related interpeak amplitudes is probably connected with interindividual differences in N2 morphology (separate peak or only step on N1-P3 deflection). Therefore P2-N2 and N2-P3 amplitudes were excluded from further analysis.

Eleven patients exhibited prolonged (+2 s.d.) P300 latencies in paradigm 4, and nine of them had prolonged latencies of P300 also in paradigm 2 and/or 3.

In control subjects, P300 latency in paradigm 4 was the only measure which correlated with age (latency = 249 + 3.05 × age, $P<0.025$). No correlation with age was found in the patient group.

Neuropsychological battery

Controls performed better than patients on each item and scored higher on each index of the neuropsychological battery. The significance was always very high ($P<0.001$), except for WB digit span and block design ($P<0.01$).

Since most of the items were correlated with each other, the scores were submitted to a principal component analysis (PCA) separately for the schizophrenic and the control group in order to obtain the main orthogonal factors to be correlated with other variables. A detailed analysis of these results is beyond the aim of the present paper and is presented separately (Romani *et al*, 1987).

Briefly, both in control subjects and in the schizophrenic group, the first two factors accounted for about 50% of the variance or more. The first factor (C1), which explained

38% of the variance in the control group and 37% in the schizophrenic group, was in both cases a general, unipolar factor which correlated significantly with almost every item of the neuropsychological battery.

The second (C2) was a bipolar factor, the relevance and meaning of which showed some differences between the two groups. In the control group, where it could explain 26% of the variance, it had the largest positive loadings on non-verbal items such as WMS picture reproduction, WB picture arrangement, picture completion, block design, object assembly and PM 38, while the largest negative loadings lay on more verbal-related items such as WMS associations, WB information, comprehension and vocabulary. TP also had a high negative loading. Among schizophrenics the meaning of C2 (which accounted for only 12% of the variance) was less evident. The largest positive loadings lay on WB digit-symbol and object assembly, while WMS associations, logic memory and WB picture arrangement had the largest negative loadings. This factor seems to tap a dimension related on the one hand to spatial-perceptive functions (in a manner similar to but not as evident as that seen in controls) and on the other hand to a verbal as well as non-verbal ability to use logic relationships in more integrated contexts.

CT scan

Mean values of CT scan measures are reported in Table II. Among the patient group, abnormal (+2 s.d.) values of both V-index and third ventricle width were found in three subjects, abnormal values of V-index alone in two subjects, and abnormal values of C-index in one subject. In the control group there was no correlation between the three measures, whereas in the patient group the measures were correlated as follows: V-index with C-index, $r_s = 0.64$, $P < 0.01$; C-index with third ventricle, $r_s = 0.67$, $P < 0.01$; V-index with third ventricle, $r_s = 0.78$, $P < 0.001$.

TABLE II
Mean values of CT scan measures for schizophrenics (S) and controls (C)

Subjects	*V-index*[1]	*C-index*[2]	*3rd vent.*[3] *(mm)*
C	12.8	2.8	1.1
S	14.3*	3.3	1.6**

1. Ventricular index.
2. Cortical index.
3. Width of third ventricle.

Relations between variables

ERPs and neuropsychological battery

Multiple regressions were performed between the factors C1 and C2 (derived from the PCA of the neuropsychological scores) and single ERP measures, which were considered as dependent variables. Possible relations with neuropsychological measures could be expected in the case of late components only, (N2, P3 latencies, N1–P3 amplitudes), and not earlier, primarily stimulus-related components (N1, P2 latencies, N1–P2 amplitudes). Therefore two opposite hypotheses were tested. Multiple determination coefficients (R^2) were considered significant when greater than 0.42 ($P < 0.01$). Also, R^2 values greater than 0.30 ($P < 0.05$) are reported, as they may show 'borderline' significant associations. As C1 and C2 are orthogonal factors, R^2 can be expressed as the sum of their single contributions.

For control subjects, no significant relation was found between ERPs and neuropsychological measures.

For schizophrenic subjects, significant R^2 values were found with P3 latency in paradigm 4 ($R^2 = 0.58$; 0.32 explained by C1, and 0.26 by C2), and with P3 latency in paradigm 2 ($R^2 = 0.45$; 0.35 explained by C1, and 0.10 by C2). There was only a 'borderline' association of P3 latency in paradigm 3 with neuropsychological measures ($R^2 = 0.35$; 0.22 explained by C1, and 0.13 by C2), and similar associations were observed for N1–P2 amplitude in paradigm 4 ($R^2 = 0.39$; 0.30 explained by C1, and 0.09 by C2) and in paradigm 2 ($R^2 = 0.39$; 0.33 explained by C1, and 0.06 by C2). In each of these relations a prolonged P3 latency or a reduced N1–P2 amplitude was associated with low values of the general factor C1 (globally poor neuropsychological performance) and with positive values

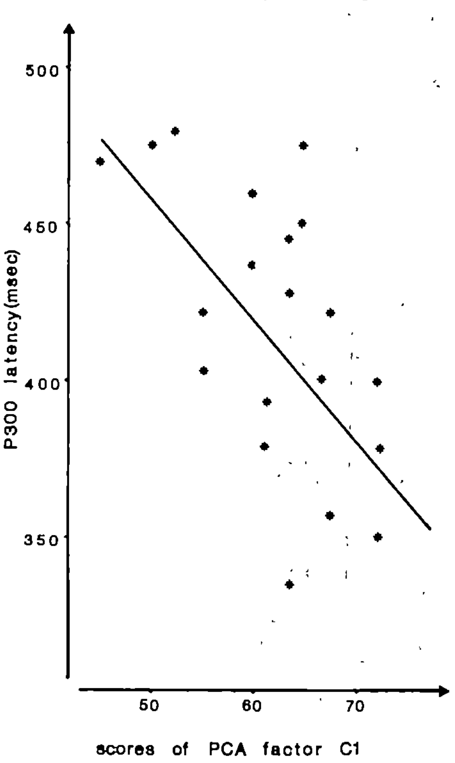

FIG. 2 Relation of P300 latency in paradigm 4 to neuropsychological performance expressed by PCA general factor C1. The regression line (latency = 630–3.44C1; $P < 0.01$) is also shown.

of the bipolar factor C2 (better on spatial–perceptive tasks than on tasks requiring more integrated verbal and non-verbal logic abilities).

It appears that the PCA factor which was most consistently associated with neuropsychological measures was the general factor, C1. For C2, the only significant relationship ($P<0.01$) was with P300 latency in paradigm 4. The relationship of P300 latency in paradigm 4 with factor C1 is represented in Fig. 2 as a simple regression. Considering the correlation coefficients between neurophysiological measures and scores of single items as indices, the most significant values ($P<0.001$) were found between P300 latency in paradigm 4 and WMS MQ ($r=0.78$), logic memory ($r_s=0.76$) and WB performance IQ ($r=0.70$).

ERPs and CT scan

Only 'borderline' significant ($0.01<P<0.05$) correlations between ERPs and CT scan were observed, and only in the case of N1–P2 amplitudes. In paradigm 1 this amplitude measure correlated with V-index ($r=0.49$) and third ventricle ($r_s=0.50$), and in paradigm 4 it correlated with C-index ($r_s=0.47$) and third ventricle ($r_s=0.52$). The correlation coefficients were always positive.

CT scan and neuropsychological battery

No correlation between CT scan and neuropsychological battery was found.

Differences between diagnostic subgroups

ERPs

P300 latency in paradigm 4 was significantly greater in disorganised schizophrenic subjects (474.4 ms) than in either paranoid (410.5 ms, $P<0.02$) or residual schizophrenics (395 ms, $P<0.001$), in spite of the fact that the disorganised subjects were significantly younger (37 years) than paranoid (43.5 years) and residual subjects (44 years). Disorganised schizophrenics also had smaller amplitudes than residual schizophrenics: N1–P2, 12.8 μV *v.* 19 μV ($P<0.05$) in paradigm 1 and 11 μV *v.* 18.2 μV ($P<0.02$) in paradigm 2; N1–P3, 14.2 μV *v.* 23.2 μV ($P<0.02$) in paradigm 2 and 11 μV *v.* 18.9 μV ($P<0.02$) in paradigm 4.

Neuropsychological battery

Disorganised schizophrenics performed worse than residual schizophrenics on the following items: WMS MQ 88 *v.* 109 ($P<0.01$); information 4.2 *v.* 5.3 ($P<0.05$); WB verbal IQ 99 *v.* 107 ($P<0.02$); performance IQ 85.4 *v.* 94.6 ($P<0.01$); full scale IQ 87.2 *v.* 101.5 ($P<0.01$); vocabulary 9.6 *v.* 14 ($P<0.01$); digit span 7.2 *v.* 8.8 ($P<0.05$); arithmetics 5.4 *v.* 6.7 ($P<0.05$); picture arrangement 4.4 *v.* 8.2 ($P<0.01$); picture completion 8.4 *v.* 9.7 ($P<0.01$). Also the general factor C1 derived from the PCA was lower in disorganised than in residual schizophrenics: 54.5 *v.* 64.8 ($P<0.01$). The bipolar factor C2 did not differ significantly between diagnostic subgroups.

CT scan

There was no difference in CT scan measures between diagnostic subgroups.

Differences between schizophrenics in terms of family history

ERPs and neuropsychological battery

When subjects were divided according to whether their family history was positive or negative, no differences in ERP and neuropsychological measures were found between the groups.

CT scan

The mean V-index was greater ($P<0.05$) among subjects with a negative family history (15.5) than among subjects with a positive family history (12.8). There was no difference in mean values of C-index and third ventricle width, but the three subjects with a dilated third ventricle all had a negative family history.

Discussion

A global impairment of intellectual function seems to be a feature of our long-stay schizophrenic patients and confirms previous reports (Heaton *et al*, 1978). Items primarily related to attention (i.e. Toulouse–Pieron), memory (digit span) and more integrated verbal (logic memory, arithmetics) and non-verbal (Raven's Progressive Matrices) functions are equally compromised; moreover, patients included in the diagnostic subgroup of disorganised schizophrenia obtained the lowest scores.

Although the selection criteria excluded the possibility that our patients might have suffered from mental subnormality, and the education of patients and controls did not differ, a control group composed of healthy volunteers might not reveal illness-specific patterns, as the long period of hospitalisation would itself represent an interfering variable (Smith, 1964), possibly more relevant than neuroleptic treatment itself (Small *et al*, 1972). Indeed, Taylor & Abrams (1984) reported in a recent study on cognitive impairment in schizophrenia that the differences in neuropsychological performance were unrelated to neuroleptic and other treatments. Also, Robertson & Taylor (1985) found neither significant differences nor even trends that could differentiate the neuropsychological performance of treated and untreated schizophrenics.

ERP measures confirm previous observations of reduced amplitudes (Roth *et al*, 1972; Verleger & Cohen, 1978; Duncan-Johnson *et al*, 1984) as well as more recent findings of prolonged latencies (Pfefferbaum *et al*, 1984) in schizophrenics. The latter authors examined patients both on and off neuroleptic medication and did not report any difference; therefore neuroleptic treatment is unlikely to account for these ERP abnormalities. Amplitude reduction does not seem to be a specific feature of the P300 component, as N1–P2 is also reduced in the three paradigms involving selective attention; and this phenomenon does not seem to be restricted to such complex situations, as it is evident in paradigm 1, in which only one kind of stimulus is presented. An analogous finding of N1 amplitude reduction in schizophrenic patients in auditory ERP paradigms which did not involve selective attention has been described by Roth *et al* (1980) for relatively long interstimulus intervals.

In contrast, latency increase involves exclusively the late components (P300 and, to a lesser degree, N2), necessarily linked to the more complex paradigms. ERPs obtained from paradigms involving different selective-attention tasks show some specific features (see also Romani *et al*, 1984). P300 latency is some 10% greater in the intensity discrimination paradigm (4) than in paradigms where a right–left discrimination is requested (2 and 3), both in control subjects and in schizophrenics (in each group $P<0.001$). Moreover, in controls a significant correlation of P300 latency with age was observed only in paradigm 4. Finally, this paradigm seems to be the one which is most sensitive in discriminating schizophrenic subjects from controls. These observations are probably not independent and suggest that mechanisms involved in discriminating this relatively small intensity difference (20 dB) on the one hand, and the side of origin of the stimuli on the other, may be partially different, the first process being more time-consuming and more influenced by age and by schizophrenic pathology.

Our CT scan measures are in agreement with the majority of reports about lateral ventricle dilatation in schizophrenia (Johnstone *et al*, 1978; Weinberger *et al*, 1979; Reveley *et al*, 1984; Owens *et al*, 1985). Although statistically significant, the dilatation was never severe (highest value of V-index 21) and involved about one-quarter of our subjects. Third ventricle dilatation was also present in our sample and confirms similar findings of other authors (Tanaka *et al*, 1981; Nybäck *et al*, 1982; Okasha & Madkour, 1982). Moderate cortical atrophy (C-index 7) was present in one patient.

The correlations between CT scan measures, and particularly between V-index and third ventricle width, observed exclusively among schizophrenic subjects, confirm similar findings described by Rieder *et al* (1983), although this author does not report third ventricle measures and does not make any statement about possible correlations in control subjects. The presence of these correlations suggests the possibility that only a subset of patients may exhibit a rather diffuse atrophy, involving primarily deep structures.

The observation that ventricular atrophy seems to be a specific feature of schizophrenic subjects with negative family history for major psychiatric disorders emerged as a collateral finding of our investigation, but is particularly intriguing considering recently published studies (Reveley *et al*, 1984; Schulsinger *et al*, 1984). These authors hypothesise on the basis of similar findings that genetic as well as environmental factors may lead to the development of schizophrenia. The subjects who have a high 'genetic load' (positive family history) may become schizophrenic with little or no environmental contribution, whereas those with a lighter 'genetic load' may require greater environmental influence (e.g. birth trauma), leading also to cerebral damage, as evidenced by signs of atrophy on CT scan. In our sample we were able to find a history of birth trauma in only one subject, who had ventricular enlargement, but other pre- or post-natal events may constitute environmental predisposing factors (Torrey & Peterson, 1976).

The analysis of the relations between measured variables revealed a consistent association between neuropsychological performance and P300 latency. The general neuropsychological factor derived from a principal component analysis – and correlated with almost every single item – accounts for the largest part of this relationship. The highest R^2 value is found in the multiple regression having P300 latency of paradigm 4 as dependent variable. This suggests that this intensity-discrimination paradigm may be more valuable in exploring cognitive functions than right–left discrimination paradigms.

The association of poor neuropsychological performance with prolonged P300 latency has been found exclusively in schizophrenics. We feel that this association is unlikely to be due to treatment, since neuroleptics have been shown to have little effect on both neuropsychological test results and ERPs (see above). Furthermore, drug treatment of our group was rigorously uniform. This relation between neuropsychological performance and P300 latency may be partially due to heterogeneity among diagnostic subgroups, since disorganised schizophrenics had the longest latencies of P300, and the lowest amplitudes, and scored lowest on most neuropsychological tests. The trend towards an association between neuropsychological PCA factors and N1–P2 amplitudes (lower amplitudes in patients with poorer neuropsychological performance) is only partially surprising, since N1 amplitude is known to be in some way related to attention (Baribeau-Braun *et al*, 1983).

The relationship between CT scan signs of atrophy and poor performances on neuropsychological tests reported by some authors (Golden *et al*, 1980; Donnelly *et al*, 1980) was not confirmed by other authors (Weinberger *et al*, 1979; Nasrallah *et al*, 1982) and was not found in our sample. This may be due to a different neuropsychological approach as well as to differences in patient population.

The few positive correlations found between N1–P2 amplitude and some CT scan measures are somewhat difficult to explain and need replication. Nevertheless, one has to consider that analogous findings have been described for the visual evoked potential of elderly and demented patients (Cosi *et al*, 1982).

In conclusion, our findings suggest that the two different instrumental approaches to the problem of schizophrenic cognitive function are clearly not equivalent. Both show some abnormal features, but while ERP measures, and particularly P300 latency, clearly parallel the actual neuropsychological performance, this is not the case with cerebral atrophy measures. The latter may be more related to the pathogenesis of the disease.

Selective Decreases in MAO-B Activity in Post-Mortem Brains from Schizophrenic Patients with Type II Syndrome

F. OWEN, T. J. CROW, C. D. FRITH, J. A. JOHNSON, E. C. JOHNSTONE,
R. LOFTHOUSE, D. G. C. OWENS and M. POULTER

The activities of the A and B forms of the enzyme monoamine oxidase (MAO, E.C. 1.4.3.4) have been assessed with the substrates 5-hydroxytryptamine and benzylamine respectively in seven areas of the brains of 39 patients with schizophrenia and 44 control subjects. Whereas previous studies have found the enzyme unchanged in brain in schizophrenia, in this study there was a modest but significant decrease in the activity of MAO-B in frontal and temporal cortices and in amygdala. This decrease could not be accounted for by neuroleptic medication, age, sex or post-mortem variables. In a series of 22 patients who had been assessed in life, the reduction in MAO-B activity was found to be associated specifically with the presence of negative symptoms (flattening of affect and paucity of speech). The findings are therefore consistent with other evidence for structural and neurochemical change in the temporal lobe that have been associated with the type II (defect state) syndrome of schizophrenia. The change in enzyme activity is unlikely to be related to a change in monoamine metabolism but may reflect a disturbance in glial function. The change in MAO-B activity in brain in this study is confined to particular areas of brain and a subgroup of patients; it is thought to be entirely unrelated to earlier reports of reductions of enzyme activity in platelets, which are probably attributable to prolonged neuroleptic medication.

Monoamine oxidase (MAO, monoamine O_2 : oxidoreductase, E.C. 1.4.3.4) has been classified into MAO-A and MAO-B on the basis of sensitivity to inhibition by specific inhibitors. Type A MAO is relatively sensitive to inhibition by clorgyline (Johnston, 1968) and Type B MAO to inhibition by deprenyl (Knoll & Magyar, 1972). In this classification of MAO, 5-hydroxytryptamine (5HT) has been described as a specific substrate for MAO-A (Johnston, 1968) and benzylamine a specific substrate for MAO-B (Christmas *et al*, 1972).

The interest in MAO in relation to schizophrenia arose from reports that the enzyme in platelets has features in common with the enzyme in liver and brain (Robinson *et al*, 1968), and that activity in platelets is reduced in patients with chronic schizophrenia (Murphy & Wyatt, 1972). The latter finding stimulated much subsequent work (see Wyatt *et al*, 1979, 1980; DeLisi *et al*, 1982; Gattaz, 1983) but the meaning has remained unclear. Because platelet MAO was found to be unchanged in populations of patients who had not received neuroleptic drugs (Friedman *et al*, 1974; Takahashi *et al*, 1975; Owen *et al*, 1976; Mann & Thomas, 1979) and particularly because, more recently, enzyme activity has been found to decline progressively but slowly with continued neuroleptic medication (Takahashi *et al*, 1975; Friedhoff *et al*, 1978; DeLisi *et al*, 1981; Owen *et al*, 1981) it has appeared increasingly likely that this variable accounts for the low levels sometimes observed in patients with schizophrenia and for the discrepancies in the literature (Belmaker, 1984).

The possible implication of a reduction in enzyme activity in platelets is that it might reflect low MAO activity in the brain. However, this suggestion has not been confirmed in the investigations of brain MAO activity reported to date. Most studies have reported MAO activity unchanged in brains of schizophrenics (Vogel *et al*, 1969; Domino *et al*, 1973; Wise *et al*, 1974; Schwartz *et al*, 1974; Cross *et al*, 1977; Crow *et al*, 1979; Reveley *et al*, 1981). However, Birkhauser (1941) reported MAO activity to be increased in the pallidum of schizophrenics and Utena *et al* (1968) reported an altered regional distribution in MAO activity in brain. In addition Fowler *et al* (1981) reported an increased MAO-B : MAO-A ratio in the pons of patients with chronic schizophrenic and non-schizophrenic psychoses. However, it is arguable that in none of these studies has a sufficient number of brains or a sufficient number of brain regions been studied to identify selective MAO changes in schizophrenia or to identify a possible subgroup of the illness with abnormal MAO activity. In the present study, therefore, we have investigated MAO-A and MAO-B activity in seven brain regions from 44 controls and 39 schizophrenics. The results were analysed with respect to age, sex, storage time at 4°C prior to autopsy, storage time deep-frozen in liquid nitrogen, neuroleptic medication, and diagnosis.

Materials and methods

Chemicals

Benzylamine and 5-hydroxytryptamine creatinine sulphate were obtained from the Sigma Chemical Company. [^{14}C]-benzylamine and [^{14}C]-5-hydroxytryptamine were obtained from the Radiochemical Centre, Amersham. All other chemicals used were from British Drug Houses Ltd, and were of the highest grade available.

Post-mortem tissue

Brains from schizophrenics were obtained at autopsy from hospitals in north-west London and occasionally further afield in southern England. They were included in the study only if the information in the case-notes fulfilled the criteria for definite schizophrenia both as defined by Feighner *et al* (1972) and as defined in the Present State Examination (PSE; Wing *et al*, 1974). For statistical analyses the schizophrenic group was divided according to whether the Nuclear Syndrome was present ($n=28$) or absent ($n=11$) as defined in the PSE syndrome check-list. In addition 22 patients in the schizophrenic group were assessed during life for the presence of positive (hallucinations, delusions, thought-disorder) and of negative (affective flattening, poverty of speech) symptoms using the rating scale devised by Krawiecka *et al* (1977). These patients were then subdivided (Crow, 1980) on the basis that they exhibited either positive symptoms alone (the type I syndrome) or negative symptoms (possibly with positive symptoms also) (the type II syndrome).

Brains were deep-frozen as soon as possible after removal from the cranium, in polystyrene moulds that retained approximate brain shape to facilitate later dissection. At dissection brains were sliced into coronal sections about 0.5–1.0 cm thick. The sections were laid flat on aluminium foil in a cooling tray and the required areas dissected out according to the atlas of DeArmond (1974) and stored over liquid nitrogen. Control brains were obtained from a large district general hospital and dissected and stored as described for schizophrenics. The data relating to the brains is presented in Table I. The schizophrenic group was a little younger, had spent less time at 4°C prior to autopsy, and slightly less time stored over liquid nitrogen than the control group.

Values as mean±s.e.

Assay of MAO activity

The activity of MAO in brain samples was determined by a technique based on that described by Robinson *et al* (1968). Brain samples were homogenised in 30 vol. of 50 mmol/l phosphate buffer, pH 7.2, using a MSE motor-driven homogeniser with a Teflon pestle. Reactions were carried out in plastic Eppendorf tubes in a total volume of 200 μl consisting of 50 μl of homogenate, 20 μl of radioactive substrate and 130 μl of 50 mmol/l phosphate buffer, pH 7.2. Initial studies were carried out on samples of putamen and hypothalamus from eight controls and six drug-free and six drug-treated schizophrenics to determine the effect of neuroleptic medication on the Michaelis Constants (K_m) and maximum reaction velocities (V_{max}) using 5HT and benzylamine as substrates for MAO-A and MAO-B respectively. Drug treatment had no apparent effect on K_m or V_{max} with either substrate. Therefore, MAO activity was assessed in seven brain regions with substrate concentrations of 1.0 mmol/l for both 5HT and benzylamine. Reactions were carried out at 37°C for 30 minutes and then terminated by the addition of 50 μl of 6 mol/l HCl to the reaction mixtures. Deaminated benzylamine products were then extracted into 500 μl of toluene and the deaminated products of 5HT into 500 μl of toluene/ethylacetate (1:1 v/v). After brief centrifugation (8000 *g*, for 2 minutes) 250 μl of the organic phase was transferred to scintillation vials, followed by 10 ml of a Triton X100/Toluene-based scintillant, and the radioactivity determined by liquid scintillation spectrometry. Homogenate proteins were determined by a phenol reagent method (Sutherland *et al*, 1949), and results were expressed as nanomoles of product formed per milligram of protein per 30 min. Extraction efficiencies for the deaminated products of benzylamine and 5HT were 95% and 83% respectively and the results presented have been corrected for recovery.

Results

An initial analysis of covariance showed that there were significant decreases in MAO-B but not MAO-A in frontal cortex, temporal cortex and amygdala of schizophrenics compared with controls. However, there were significant effects of age and sample storage time deep-frozen on both MAO-A and MAO-B activities in most brain regions. The relationship between age and MAO-A and MAO-B obtained by linear regression analysis is presented in Table II. Storage time at 4°C prior to autopsy, sex of the subjects and neuroleptic medication were without significant effect on MAO-A or MAO-B activities. The results of the regional distribution of MAO-A and MAO-B activities presented in Figs 1 and 2, therefore, are adjusted by analysis of covariance with enzyme activity as the dependent variable

and age and deep-frozen storage time as covariates. This analysis confirmed that there were significant reductions in MAO-B activity in frontal cortex, temporal cortex and amygdala in the schizophrenic patients. Further analysis showed that this MAO-B deficit was specific to type II

TABLE III

MAO-B activity in type I and type II schizophrenics

schizophrenics (Table III), although the decrease just failed to reach significance in the amygdala, and unrelated to the presence or absence of the Nuclear Syndrome as defined in the PSE.

Discussion

The reductions in MAO-B activity found in the present study in frontal cortex, temporal cortex and the amygdala of schizophrenic post-mortem brain has not been found in earlier studies (e.g. Cross *et al*, 1977; Reveley *et al*, 1981). This result only emerged after an analysis of covariance and may well depend upon the larger sample size of the present as compared to previous studies. However, the reduction in MAO-B activity observed in the present study can hardly be advanced in support of the suggestion that low MAO activity favours the development of schizophrenia (Murphy & Wyatt, 1972). The decrease was selective to patients with negative symptoms and unrelated to the presence or absence of the Nuclear Syndrome as defined by Wing *et al* (1974). In addition, Greene & Grahame-Smith (1978) have demonstrated that MAO is not a rate-limiting enzyme in monoamine metabolism, and the relatively small decreases in MAO-B observed in the present study would not be sufficient to alter central monoamine concentrations. Moreover, it is thought that MAO-B is mainly extraneuronal and MAO-A mainly intraneuronal in rat and human brain (Oreland *et al*, 1983). Thus the MAO-B deficits are most unlikely to be relevant to neurotransmitter metabolism. For the reasons given in the introduction, the deficit is also unlikely to be related to changes in MAO activity in platelets, which are probably secondary to neuroleptic medication.

MAO-B activity, but not MAO-A activity, has been reported to be increased in brains from patients dying with Alzheimer's disease (Adolfsson *et al*, 1980) and also after hemitransection of the brain in the rat (Oreland *et al*, 1980), in both of which cases there is proliferation of glia in the degenerating parts of the brain. Similarly, Fowler *et al* (1981) reported increased MAO-B : MAO-A ratio in schizophrenics compared with controls in samples from the pons (but not other areas), and suggested that the increased ratio resulted from neuronal loss. The results of the present study are not consistent with Fowler's suggestion. It can be seen by inspection (Figs 1 and 2) that MAO-B : MAO-A ratios were decreased rather than increased in most brain regions studied.

MAO-B activity, measured with B-phenylethylamine as substrate, has been reported to be decreased in 12 out of 13 brain regions studied in samples from suicide victims (Gottfries *et al*, 1974). The selective decrease in MAO-B activity in certain brain regions of patients with the type II (defect state) syndrome, therefore, is unlike the more general decrease found in brains of suicides.

The initial kinetic studies on samples from controls and drug-free and drug-treated schizophrenics revealed, firstly, that there were no gross differences between controls and schizophrenics in the V_{max} or K_m of MAO with either 5HT or benzylamine as substrate, and secondly, that neuroleptic medication had no effect on V_{max} or K_m values. An analysis of covariance in the larger series of samples confirmed the lack of effect of neuroleptic medication on MAO-A or MAO-B activity in any of the seven brain regions studied. This is consistent with a previous report (Eckert *et al*, 1980).

A positive correlation between MAO-B and age (Table III) was found, as previously reported for human (Robinson *et al*, 1972; Fowler *et al*, 1981) and rat brain (Benedetti & Keane, 1980). When controls and schizophrenics were considered together, MAO-B activity correlated significantly with age in all brain regions. MAO-A activity was less strikingly related to age, although significant correlations were found in the caudate and putamen of both controls and schizophrenics, and in caudate, putamen and temporal cortex when controls and schizophrenics were considered together. It is unlikely that the relatively high substrate concentrations used in the assay procedure resulted in a loss of substrate specificity, since it has been clearly demonstrated that 5HT and benzylamine remain specific substrates for MAO-A and MAO-B respectively over a very wide range of concentrations (Suzuki *et al*, 1979). Moreover, in the initial kinetic study the ratio of MAO activity towards 5HT and benzylamine did not alter over the range of concentration used. It may be that a large sample is necessary to demonstrate this weak relationship between MAO-A and age. In the present study the schizophrenic group was a little younger than the control group but this age difference was taken into account in the analysis of covariance.

MAO activity was unaffected by the sex of samples or the length of time cadavers were at 4°C in the mortuary prior to removal of the brain from the skull. The post-mortem stability of brain MAO has been demonstrated with experimental animals (Fahn & Cote, 1976). However, there was a significant decline in MAO activity after prolonged storage over liquid nitrogen in all brain regions studied in both controls and schizophrenics. The effect of storage time on MAO activity was also taken into account in the analysis of covariance.

The selective MAO-B changes in frontal and temporal cortex and amygdala in patients with the type II syndrome found in the present study are unlike any previous findings in brain samples from individuals dying from various neuropsychiatric conditions. These changes either reflect, rather than mediate, changes in monoamine function, as suggested by Gottfries *et al* (1974) to explain the decreased MAO activity in brains of suicides, or are part of a more general biochemical pathology in these particular brain regions. Monoamine oxidase is situated in the outer mitochondrial membrane, and an investigation of other mitochondrial markers in brain samples from schizophrenics seems worthwhile. The findings add to other evidence of structural (Brown *et al*, 1986) and neurochemical (Ferrier *et al*, 1983; Reynolds, 1983) changes in the temporal lobe in schizophrenia and emphasise that such change may be particularly associated with poor outcome.

A Comparison of Scales for Assessing Rehabilitation Patients

ROBIN G. McCREADIE, JAMES W. AFFLECK, YVONNE McKENZIE and ANDREW D. T. ROBINSON

Twenty-four chronic schizophrenic patients were assessed by the Morningside Rehabilitation Status Scale, the Krawiecka Scale, and the Social Adjustment Scale by Self-Report. Inter-rater correlations suggest that the MRSS can be used by a rater with little previous knowledge of the patient. Between-scale correlations suggest the three scales assess somewhat different dimensions. A standard approach to rehabilitation assessment is suggested.

Assessment of patients who pass through rehabilitation services is necessary if progress is to be accurately charted. A new assessment scale, the Morningside Rehabilitation Status Scale (MRSS) (Affleck & McGuire, 1984) covers a wide range of rehabilitation problems, yet can be readily used in a busy NHS rehabilitation service. The scale examines rehabilitation status over the previous month in the dimensions of independence/dependence; activity/inactivity; social integration/isolation; and the effect of symptoms. However, once a scale is published, further work should be undertaken to learn more about its properties, its suitability for use with various populations, and how it compares with other scales (Snaith, 1981). We therefore wish to report, firstly, inter-rater reliability results in the final published version of the scale; and, secondly, a comparison of the MRSS with two established rating scales, namely the Social Adjustment Scale by Self-Report (SAS–SR) (Weissman & Bothwell, 1976) and an assessment of mental status, the Krawiecka Scale (Krawiecka *et al*, 1977).

Method

Twenty-four chronic schizophrenic day patients, 10 females and 14 males, 88% of whom fulfilled the Feighner Criteria for definite or probable schizophrenia (Feighner *et al*, 1972), were rated independently by two psychiatrists using the MRSS; one psychiatrist was in thrice-weekly contact with the patients, the other had little or no previous contact. Assessment, which took 20–30 minutes, was through interviews with the patients and discussion with senior nurses at the day hospital. The sort of information needed to complete the scales is shown in Appendix 1. On the same day, a third psychiatrist assessed patients' mental status over the previous week using the Krawiecka Scale, and within the same week patients assessed their own social adjustment over the previous two weeks using the SAS–SR. The Krawiecka Scale assesses eight schizophrenic and other symptoms: depression, anxiety, flattened or incongruous affect, retardation, delusions, hallucinations, incoherence, and poverty of speech. An assessment can be made in about 15 minutes. Its content allows the classification of patients in accordance with the Wing Scales (Wing, 1961). The SAS–SR, which takes about 10 minutes to complete, is a 54-item questionnaire which yields an overall adjustment score and a rating of six role areas: work as a worker, housewife or student; social and leisure activities; relationships with extended family; and marital roles as a spouse, parent, and member of the family unit.

Results

Correlations between raters on MRSS total and subscale scores ranged from +0.62 (for dependence) to +0.83 (total score) (Table I). The range of correlations was broadly similar to that previously found in Krawiecka scales but somewhat greater than in the SAS–SR (Table I). There were no significant between-rater differences in magnitude of scores except in the inactivity subscale of the MRSS (*t*-test; $t=2.97$, $P<0.01$).

When scales were compared (Table II), correlations between total MRSS scores and both the Krawiecka and SAS–SR scores were statistically significant, but there was no significant correlation between the Krawiecka and SAS–SR scores. With MRSS subscales, the only correlations that were statistically significant in both raters were between dependence and symptoms and Krawiecka total scores.

Discussion

Inter-rater correlations in total and subscale MRSS scores were high and suggest that an accurate rating of patients' rehabilitation status can probably be made by an external rater; although he could obtain details from staff or relatives, he had little previous knowledge of the patient. Discussion of the discrepancy in magnitude of scores in the activity/

inactivity subscale revealed contradictory rating instructions, which were subsequently modified; this supports the view that further work to improve a scale once it has been published should be undertaken (Snaith, 1981).

Correlations between scales were more variable. One general problem is in the different lengths of observation period for the three scales. Also, the different scales do not attempt to measure exactly the same dimension; for example, the MRSS symptom subscale aims at grading the effect of symptoms on the patient's lifestyle, and is not merely a straightforward mental state assessment. Another difference is that the Krawiecka Scale is aimed specifically at chronic patients, whereas the MRSS anticipates that some patients may have no symptoms at all. However, MRSS total scores correlated significantly with both the Krawiecka and SAS-SR. It was the symptom and dependence subscales that contributed most to the overall correlation with the Krawiecka; that the symptom subscale did so is not surprising, but the contribution of dependence was less expected. However, scrutiny of the information required to assess dependence (Appendix 1) shows that contact with staff is an important part of this assessment; patients with many abnormalities in their mental state will no doubt attract the attention of medical and other staff.

Correlations between the MRSS and SAS-SR, although statistically significant for both raters when total scores were compared, were in the main lower, and no subscale obviously contributed in both raters' assessment to the overall correlation. The assessment of social adjustment is obviously more hazardous. Patients' 'feelings and satisfactions' which are rated in the SAS-SR may not be tapped by the MRSS.

TABLE I
Inter-rater reliability

MRSS	*Pearson correlation (r)*	*P*
Total score	+0.83	<0.001
Dependence	+0.62	<0.01
Inactivity	+0.70	<0.001

Parental	+0.47	<0.001
Family unit	+0.40	<0.001

1. Taken from Krawiecka *et al* (1977).
2. Taken from Weissman & Bothwell (1976).

TABLE II
Pearson product-moment correlations between MRSS, Krawiecka and SAS-SR scales

MRSS	*Krawiecka (total score)*		*SAS-SR (total score)*	
	Psychiatrist 1 v. Psychiatrist 3, r	*Psychiatrist 2 v. Psychiatrist 3, r*	*Patient v. Psychiatrist 1, r*	*Patient v. Psychiatrist 2, r*
Total score	+0.67****	+0.51***	+0.46**	+0.50***
Dependence	+0.58***	+0.43*	−0.07	+0.28
Inactivity	+0.18	+0.36	+0.27	+0.29
Social integration	+0.50***	+0.36	+0.33	+0.54***
Symptoms	+0.68****	+0.58***	+0.56***	+0.20
Krawiecka			*SAS-SR (total score) Patient v. Psychiatrist 3*	
Total score	—	—	+0.16	

*$P<0.05$, **$P<0.02$, ***$P<0.01$, ****$P<0.001$.

There was no correlation between the SAS–SR and Krawiecka; these scales are obviously examining different aspects of the patient's functioning.

In conclusion, we agree with Hall (1979) that where possible more than one type of assessment should be used. The scales chosen will depend on clinical and research objectives, but it might be reasonable to consider the MRSS for overall rehabilitation status and a dimensional profile; the Krawiecka for symptoms; the SAS–SR for social adjustment from the patient's view; and perhaps (for research purposes only) the Social Behaviour Assessment Schedule (Platt *et al*, 1980) for the relative's view. This would enhance the probability of a standard approach to rehabilitation studies, but high levels of reliability and validity can only be maintained if the users of the scales know about the pitfalls and if reliabilities are assessed and discrepancies discussed.

Acknowledgements

We wish to thank patients and nursing staff for their co-operation; Mr R. J. McGuire for statistical advice; and Miss P. Cowan for secretarial assistance.

Appendix 1
MRSS information checklist

Dependency scale

How independent the patient is with regard to self-care, economics and medication

1. Living place
2. Other occupants and their role regarding patient's dependency
3. Domestic arrangements
4. How economic responsibilities are shared
5. Personal habits: hygiene, clothing, tidiness, rising routine
6. Visiting by staff
7. Medical arrangements
8. Other professional contacts if any

Inactivity (occupational and leisure) scale

How well the patient has initiated and sustained activity and performed effectively

1. Work
2. Training programme
3. Method of looking for work
4. Daily routine
5. Leisure time routine, indoor/outdoor (weekdays and weekends)
6. Reading habits and interests, TV, radio, etc.

Social integration/isolation scale

Frequency of contact and social competence

1. Companions in living place
2. Friendliness with other occupants
3. Neighbours known? how well?
4. Family members in current contact
5. Other *social* activities, games, sports
6. Social contacts at work
7. Close friends, intimate friends
8. Social difficulties or incompetence

Effects of current symptoms and deviant behaviour scale

Current problems only must be rated, i.e. only those which have occurred during the period being assessed, normally the last month.

1. Subjective symptoms
2. Other serious symptoms elicited by questions
3. Attitude to medication
4. Symptoms observed by others
5. Other unusual behaviour
6. Difficulties in organising daily routine

Extent, Timing and Persistence of Emotional Disorders following Childbirth

P. N. NOTT

A three-stage community survey of a representative group of Southampton mothers was carried out. A semi-structured psychiatric interview was administered at 3, 9 and 15 months post-partum. The results of these interviews are presented and used to assess the extent and timing of psychiatric disorders arising in this period. In contrast to previous studies, it was found that the highest incidence of *new cases*, variously defined, occurred between the third and ninth month post-partum and not immediately following childbirth. These results are discussed in the context of previous studies using the same definition of caseness.

In recent years there has been a series of attempts to estimate the extent and nature of emotional disorders following childbirth. Pitt (1968) estimated that the incidence of 'atypical depression' at 6–8 weeks following childbirth was 10.8%. He was able to follow up 28 of his depressed mothers, and at 15 months 12 were still depressed.

In his paper Pitt emphasised the importance of this finding, even if most cases had been 'mild' from a hospital-based psychiatrist's point of view. Post-natal depression appeared an unexpectedly common condition and for 4% of his population it appeared to be persistent. In fact, re-examination of Pitt's data (Neugebauer, 1983) has indicated that because he only interviewed all his probable cases to estimate incidence, Pitt underestimated the total number of cases in his population. Neugebauer recalculated Pitt's figures, taking into account the cases lost by the screening method, and estimated the incidence to be nearly 20%.

Kumar (1982), in a critical review of the most important of the studies, including his own, pointed out some of the methodological difficulties which undermined the reliability of many of the estimates of the incidence of post-natal depression. These have varied from 3% (Tod, 1964) to 30% (Rees & Lutkins, 1971).

Kumar's own study (Kumar & Robson, 1984) had attempted to overcome some of these difficulties. He and his co-workers used a standardised semi-structured psychiatric interview (SPI) (Goldberg *et al*, 1970) to define their cases, and their 114 subjects were interviewed at least three times during pregnancy and five times after delivery. However, the SPI was administered to all the subjects only on three occasions. The investigators rated as 'new' cases only those cases who had not been cases at the previous interview. Upper- or middle-class subjects were over-represented and all subjects were dutifully attending regularly a London teaching hospital clinic. All the subjects were primips. It was found that 3 months after delivery, 17% of the mothers had significant disorder, and 11.4% of the women had developed their disorder since childbirth.

Although this study has remained the most intensive so far, Kumar himself has suggested that his subjects were not representative of a normal community sample. If indeed this was an unusually healthy and resilient sample, then two things follow. Firstly, Kumar & Robson's figures are probably an underestimate of the prevalence and perhaps the severity and persistence of post-partum disorders in other populations. Secondly, the evidence supports the idea that even in relatively favourable circumstances, pregnancy and even more the months post-partum are associated with an increased risk of depression.

One further important factor mentioned by Kumar is the possible supportive effect of their frequent interviews.

In a subsidiary sample of 38 primips and 39 multips who were studied only post-partum but otherwise in an identical manner, Kumar & Robson found that, overall, 28.6% were rated cases at 6 months. One of the 38 primips developed a psychosis, and of the rest 10% were depressed at one year. Of the multips, 23% were depressed at one year.

The study described in this paper used the same criterion of caseness as Kumar & Robson but the interviews were restricted to three interviews at 3, 9 and 15 months post-partum, and included a representative sample of Southampton mothers, primips and multips. The present paper describes the findings concerned with the prevalence, persistence and timing of disorders arising in this sample.

Method

The sample consisted of all 212 mothers listed as having had babies during a 3-month period. Their names were obtained from the birth books of five Southampton group practices. Each mother was contacted by her general practitioner (GP) and informed of the study and invited to take part.

Interviews

There were three interviews, all conducted in the subject's own home at 3, 9 and 15 months post-partum. At the first interview, each mother who agreed to take part first completed the 30-item General Health Questionnaire (GHQ-30). This was then placed in a folder without being scored, and the interviewer proceeded to fill in a data sheet. Finally, the semi-structured psychiatric interview (SPI) was administered. The second and third interviews followed the same procedure, using, however, different data sheets. After the third interview the subject also completed the Eysenck Personality Inventory (EPI). The present paper presents the findings related to the SPI. The GHQ-30 data and correlates of post-natal depression will be presented in separate papers.

Semi-structured psychiatric interview

The semi-structured psychiatric interview (SPI) (Goldberg *et al*, 1970) is acceptable to people who do not consider themselves mentally ill, and is shorter than other commonly used standardised interviews. It is suitable for measuring the nature and severity of neurotic disturbance and has been used previously in studies of post-partum depression (Cox *et al*, 1982; Kumar & Robson, 1984). It is designed to elicit the presence or absence of ten defined psychiatric symptoms. In addition, twelve manifest abnormalities are looked for by the interviewer during the interview. The SPI can be used in various ways to define 'caseness'. In this study, caseness was defined by the 'overall severity rating' (OSR). At the end of the interview the subject is classified on a five-point scale: normal, 0; minor symptoms short of clinical significance, 1; symptoms warranting GP referral, 2; symptoms requiring psychiatric out-patient referral, 3; and symptoms judged to need psychiatric in-patient treatment, 4.

Inter-rater reliability

Each of the three interviews was carried out by a separate interviewer. All three interviewers and the author were trained in administering the interview at the GP Research Unit at the Institute of Psychiatry. The author supervised each stage and discussed any difficulties in rating. A note was made of any subjects considered borderline. At each stage, 12 of the subjects were interviewed by two interviewers, and the results of this separate study (Nott, 1984) indicated a high inter-rater reliability.

Results

Characteristics of the sample

Of the 200 subjects completing the first interview, the age range was 16–39 years (mean 24.8). There were 188 married women, 6 single and 6 divorced or separated. Social class distribution defined by husband's occupation was similar in our sample to that of the social class distribution of Southampton heads of household by occupation determined in the 1982 Census. The incidence of obstetric intervention and complications was similar in our sample to the incidence in all Southampton deliveries.

Prevalence of cases

Table I shows the number completing each interview and the OSR rating. The percentage of cases (OSR 2 or more) at each stage is 18.5% at 3 months, 28% at 9 months, and 31% at 15 months. It can also be seen that although the majority of cases are less severe (OSR 2, warranting GP referral), the number thought to warrant psychiatric intervention is increased at 9 months and 15 months.

Symptoms experienced by cases

Each symptom rated during the structured psychiatric interview was rated on a scale of 0 to 4. A score of 2 or more was regarded as pathological. The percentage of *cases* ($n = 37$) with a pathological score for the various symptoms at 3 months was as follows: somatic symptoms, 43%; fatigue, 68%; sleep disturbance, 49%; instability, 84%; lack of concentration, 51%; depressed mood, 78%; anxiety, 62%; phobias, 11%; obsessions, 27%; depersonalisation, 22%.

At 3 months the commonest symptoms of note were irritability, depressed mood, and anxiety. The symptom profiles were similar at all three stages of the study and confirm that post-natal *depression* is probably an appropriate name for these disorders. None of our subjects developed a psychotic illness and none was admitted to a psychiatric unit.

Caseness with time

Having three consecutive interviews at 6-month intervals, we can follow the outcome of cases and non-cases. If a past history of emotional disorder is taken as caseness prior to the study, we can illustrate the probability of recovery or onset of illness during those time intervals. Table II shows that most change is taking place between the first and second interviews, and there is an overall tendency for both cases and non-cases to retain their category with time.

New cases arising post-partum

Using the data in this study, 'new' cases can be defined in two ways. New cases (1) are defined as cases who have no

TABLE I

Chance of NC–NC	0.86	0.76	0.86

C – case, NC – non-case

history of contact with the psychiatric services and have not been rated cases at a previous stage in the study. New cases (2) are defined, even more exclusively, as cases who have no past psychiatric history at all – not even contact with a GP for emotional problems – and have not been rated cases at an earlier stage of the study. Table III gives the prevalence of 'new' cases at each interview for each of these two definitions, and the overall prevalence for comparison.

Defining new cases in this way excludes 'chronic cases' and the recruitment of cases with time as the study progressed. It can be seen that even by the strictest definition, the prevalence of new cases at each stage is considerable. Moreover, most new cases arise between 3 and 9 months, and not in the 3 months immediately following childbirth.

TABLE III

Ratios of cases to total number at each stage for all cases and 'new' cases defined in terms of past psychiatric history (see text for definitions)

Interview	*Cases/total number*		
	All cases	*New cases (1)*	*New cases (2)*
1 (3 months)	37/200 (18.5%)	32/188 (17%)	20/150 (13%)
2 (9 months)	50/173 (29%)	30/136 (22%)	20/112 (18%)
3 (15 months)	51/163 (31%)	10/94 (10.6%)	7/81 (9.5%)

Persistence of 'new case' at interview 1 with time

Interview 1 (3 months)	*Interview 2 (9 months)*	*Interview 3 (15 months)*
32 (new case (1)[1]) →	15 (case) →	11 (case)
	12 (non-case)	3 (non-case)
20 (new case (2)[1]) →	9 (case) →	8 (case)
	8 (non-case)	1 (non-case)

1. See text for definition

Outcome of new cases

By following those subjects classified as new cases at the first interview, we can determine whether these cases recover quickly or not. Table IV gives the figures for those 'new cases' at interview 1 who completed the whole study. Some subjects were lost at both the later interviews, but not enough to affect the overall picture. The table clearly shows that, defining new cases in either way, of all the new cases at first interview, about half remain 6 months later, and the majority at that stage remain cases at 15 months.

Discussion

This study shows that post-natal depression as described by Pitt (1968) is a common finding in a representative group of Southampton mothers. We have found that it is characterised by irritability, depressed mood, fatigue and a considerable degree of anxiety. It is often associated with feelings of hopelessness and an inability to cope with daily tasks. However, none of our subjects developed a psychotic illness and none was admitted to a psychiatric unit.

The lack of psychiatric involvement in the management of post-natal depression in our subjects explains our previous psychiatric case-register findings (Nott, 1982). These had indicated that psychotic disorders increased sixfold following childbirth compared with other times, to a rate of 1.15 per 1000. Referral for less severe depressive and anxiety states decreased during pregnancy, and did not increase significantly following childbirth, compared with rates prior to and during pregnancy. This underlines the fact that community studies are necessary to obtain reliable evidence of the prevalence and incidence of less severe psychiatric disorders, which are mostly not referred to the psychiatric service and so missed by case-register studies.

Even in a community survey such as this, the meaning of specific prevalence figures may remain problematical. Barker & Rose, quoted by Williams *et al* (1980) in a paper which discusses the problems of case definition, state:

> apart from a few inherited disorders . . . in the general population, disease behaves as a continuously distributed variable. The question is not so much 'has she got it?' as 'how much has she got?'

We certainly found this was so in trying to measure disorder in our subjects. However, using a standardised interview and a defined cut-off point, we can compare the same subjects at different times, and allow our subjects to be compared with different populations who have been surveyed using the same instrument.

At 3 months post-partum, our prevalence of 18.5% for cases and 13% for 'new cases' is comparable with the result of Kumar & Robson (1984), who found 16% cases and 12.6% new cases arising by 3 months after delivery. Cox *et al* (1982) found a prevalence of 13% cases at 3 months, and Watson *et al* (1984) a prevalence of 16% (12% new cases) at 6 weeks post-partum. These studies used the same standardised psychiatric interview as the present study.

Our survey shows that the number of subjects rated as cases is greater at 9 months than at 3 months, and this increase persists at 15 months. We have previously shown that this is not due to the recruitment of chronic cases with time. The highest prevalence of new cases is at 9 months (18%): prevalence falls again to 9.5% at 15 months. The symptom profiles of the cases were similar at all three points in time.

Of our subjects who became cases for the first time post-partum (i.e. they had no previous history of emotional disorder prior to that time), half of them were still rated cases 12 months later. This tendency for cases to remain cases with time is not revealed by simple cross-sectional studies and is important. A persistent disorder is more likely to be related to adverse social and family consequences.

There is other evidence suggesting that these disorders are not shortlived. Pitt (1968), in a postal follow-up at one year post-partum, found that 12 of his 28 cases had not recovered. Feggeter *et al* (1981) carried out a survey of women one year after childbirth, using the General Health Questionnaire (Goldberg, 1972) as a screening instrument and the Present State Examination (Wing *et al*, 1974) to define caseness: they found that for those rated cases, the duration of the disorder assessed retrospectively from the time of interview was over one year in 13% and one year or slightly less in 35%. Kumar & Robson (1984) found that at 4 years post-partum, 14 of the 16 cases rated at 3 months post-partum were still available for interview: 6 of these, almost half, had continued to consult for emotional problems over the whole 4-year period.

Kumar & Robson (1984) found the highest prevalence of new cases to be at 3 months post-partum, thereafter dropping by about two-thirds to what they state is in line with their pre-pregnancy estimate. Watson *et al* (1984) found the highest prevalence at 6 weeks post-partum, but they do not appear to have carried out a formal SPI rating after that time. Kendell *et al* (1976), commenting on their case-register study, noted a secondary rise, "less dramatic but more sustained, from the 10th to the 24th month after delivery". This finding of a raised psychiatric consultation rate up to 2 years post-partum was supported by the finding of Kendell *et al* (1981) of a raised psychiatric admission rate for at least 2 years after childbirth in a separate case-register study. Our own findings of a peak prevalence for new cases at 9 months and a persistent high total prevalence may explain this discrepancy. In a relatively healthy population of primips it may be that those who are going to develop symptoms do so relatively soon after childbirth, but for multips and others, symptoms develop later. In either case, for a significant number the symptoms are liable to be persistent, and these 'chronic' cases are those most likely to be referred for psychiatric help at a relatively late stage, when primary health care measures have failed.

These studies do not answer the following question: are prevalence rates post-partum greater than those found in a general population sample of non-post-partum women? No study of puerperal women has yet included a suitable control group. Indeed, any suggested control group is likely to differ systematically from a post-partum group in numerous ways. Kumar & Robson (1984) point out that their period prevalence for the post-partum year (24%) was little different from the findings of surveys of the mental health of female attenders in general practice (Shepherd *et al*, 1966). They suggest that their figure would have been higher if they had

had a less healthy sample. In our own study, the 9-months period prevalence for new cases by our strictest criterion is 31%, a figure which supports the idea that the post-partum year is a particularly vulnerable period.

The only comparison we can make at present with a general population survey using the same standardised psychiatric interview is to compare our prevalence rates for all cases with those of Hobbs *et al* (1983). They carried out a survey of 1517 women aged 20–60 years using the General Health Questionnaire. They then arrived at estimated prevalence rates by interviewing subsamples of high scorers and low scorers. They used the same semi-structured psychiatric interview (SPI) as the present study. Using the overall severity rating as in this study, they found an estimated prevalence rate of 26%. This can be compared with our prevalence rates for all cases of 18.5%, 28% and 31% at our three interviews.

In conclusion, we have found evidence which supports the idea that the post-partum period is a period of increased vulnerability for women, but the suggestion of a strict temporal relationship of disorder to delivery was not corroborated. This has implications for attempts to understand the cause of post-natal disorder. The findings of this study suggest that the causes of post-natal depression are more likely to be in the psychosocial aspects of the puerperium, and perhaps the mother's own predisposition in terms of personality and background, rather than in the hormonal and other physical changes associated with childbirth itself. This is in agreement with the suggestions arising from the intensive study of Watson *et al* (1984). Indeed, it again raises the question of whether in fact 'post-natal depression' is qualitatively different from depression at other stages in a woman's life.

Acknowledgements

I would like to thank Dr Paul Williams of the GP Research Unit at the Institute of Psychiatry for advice and training in the interview technique; and Drs Cutts, Booth and Sandiford, who carried out the interviews.

Familial Aspects of Obsessive–Compulsive Neurosis

PATRICK McKEON and ROBIN MURRAY

The first-degree relatives of 50 obsessive–compulsive patients and those of matched controls completed the General Health Questionnaire (GHQ) and the Leyton Obsessional Inventory (LOI). Relatives who were identified as possible 'cases' by their high GHQ scores, or by their own or informant relatives' reports, were interviewed using the Schedule for Affective Disorders and Schizophrenia. Index relatives had a significantly higher lifetime prevalence of mental illness (36%) than had those of controls (17%), due mainly to an excess of depressive and neurotic disorders. However, only one relative from each group was diagnosed as having definite obsessive-compulsive neurosis. In addition, the LOI scores were similar for the index and control relatives.

Studies of the relative contributions of heredity and environment to the development of obsessive–compulsive neurosis have, in the absence of biological markers, centred on twin and family investigations. The present study was undertaken to determine the prevalence of obsessive–compulsive neurosis at a clinical and psychometric level in the first-degree relatives of probands with this disorder, and to examine the effect of the degree of kinship and birth order on obsessional symptoms.

Most twin studies point to a higher concordance rate for obsessive–compulsive neurosis for monozygotic (MZ) pairs than for same-sex dizygotic (DZ) pairs. However, such findings need to be interpreted cautiously, in view of (a) the bias in the selection and reporting of cases, (b) the use of unsatisfactory diagnostic criteria, (c) the diagnostic bias introduced when the researcher is aware of the twins' zygosity, and (d) the fact that zygosity is not always fully established. These points are emphasised by the conflicting conclusions of two reviewers of the same literature. Carey (1978) noted that there were 30 concordant and 13 discordant MZ twin pairs, compared with no concordant and 14 discordant DZ pairs. Black (1974), however, concluded that in only three published instances of identical twins with obsessive–compulsive neurosis was the zygosity and diagnosis reliably determined. More recent twin studies continue to report disparate findings (Carey & Gottesman, 1981; Torgensen, 1983), and although they indicate a higher concordance rate for MZ than for DZ twins for neurotic disorders, they question the idea that specific neurotic disorders breed true.

While the overall trend of family studies for obsessive–compulsive neurosis indicates familial aggregation, some investigations provide insufficient detail (Lewis, 1936), or lack control data (Rudin, 1953; Rosenberg, 1967) or agreed operational criteria (Brown, 1942; Kringlen, 1965), thus making the reliability of their findings less certain. However, the results of three studies bear comparison. Brown (1942) found that, compared with controls, the parents of obsessive–compulsive patients had a significantly increased incidence of obsessional neurosis (8%), as did the patients' siblings (7%). Rudin (1953) reported finding obsessive–compulsive features in 4.6% of parents and in 2.3% of siblings of obsessive–compulsive patients. Both these studies produced higher familial rates of obsessive–compulsive disorders than that of Rosenberg (1967), who found among 547 first-degree relatives only two cases of obsessional neurosis. The diverging familial rates probably reflect the different diagnostic criteria used.

Psychometric investigations of families of obsessive–compulsive patients have been limited to three studies (Coppen *et al*, 1965; Rosenberg, 1967; Insel *et al*, 1983). Coppen and his associates administered the Maudsley Personality Inventory (MPI) to relatives of patients with neurotic illness, of whom 19 had obsessional neurosis, and found that the familial level of neuroticism was lower than that quoted for normal subjects. Rosenberg (1967) reported that the mean neuroticism score on the MPI for the first-degree relatives of obsessional probands was slightly below the accepted norm.

The only psychometric study specifically of obsessionality is that of Insel *et al* (1983). They found that mean Leyton Obsessional Inventory symptom scores for the parents of ten obsessive–compulsive patients did not differ from normative data.

Abnormal pre-morbid personality traits have been noted in some two-thirds of those who develop obsessive–compulsive neurosis (Pollitt, 1960;

McKeon, 1983). If indeed obsessional neurosis has a familial tendency, the possibility of this being reflected in a latent form in the patients' pre-morbid personalities could be usefully explored by examining the relationship between the extent of familial clustering and degree of personality abnormality.

In this paper we report the prevalence and type of psychiatric morbidity among the first-degree relatives of probands with obsessive–compulsive neurosis and a matched control group, and examine the relationship between the extent of familial clustering of mental illness and the probands' pre-morbid personalities. Psychometric scores for obsessionality, phobias and psychiatric morbidity for index and control families are compared, and the effect of degree of kinship and ordinal birth position on obsessional symptoms is studied.

Method

Obsessive–compulsive probands

Index probands were consecutive attenders at the Maudsley and Bethlem Royal Hospitals' behaviour therapy unit who had received from their treating psychiatrist a primary diagnosis of obsessive–compulsive neurosis (300.3 in the International Classification of Diseases (ICD) (World Health Organization, 1975)), and who met the operational definition of the Research Diagnostic Criteria for obsessive–compulsive neurosis (Spitzer *et al*, 1978). Those agreeing to participate in the study had to have living first degree-relatives whom they consented to have interviewed, none of whom was already included as a proband. The first 50 patients meeting these criteria formed the obsessive–compulsive proband group. One subject who met the diagnostic criteria for inclusion in the study was excluded, as he declined to have his relatives interviewed.

Comparison-group probands

Controls were selected from consecutive attenders at two general-practice surgeries. Subjects agreeing to participate, who could be matched with a patient proband for sex, age (within 3 years), marital and socio-economic status (within one class on the Registrar-General's Classification), race, religion (parents' religion) and birth order, were interviewed using the Schedule for Affective Disorders and Schizophrenia – Life time version (SADS-L; Endicott & Spitzer, 1978). Those who did not meet 'case' criteria on the SADS-L were included in the study. Two matching systems were employed for birth order: one classified subjects as being either only children, first-born, middle-born or youngest, while the other was sex-related with eight categories – only boy, only girl, eldest boy, eldest girl, middle-born boy, middle-born girl, youngest boy and youngest girl. Three subjects who met the matching criteria declined to participate in the study.

Relatives

Patient and comparison-group probands were requested to distribute the questionnaires to all their first-degree relatives over the age of 16 years. The questionnaires were accompanied by an introductory letter requiring respondents to complete the forms independently and return them by post. Relatives who did not return the questionnaires within 4 weeks were written to and, where necessary, visited to encourage completion of the rating scales.

Questionnaires

General Health Questionnaire (GHQ) (Goldberg & Hillier, 1979). This 28-item version is a modified form of the original GHQ, and its sensitivity and specificity is at a maximum with a cut-off score between 4 and 5.

Leyton Obsessional Inventory (LOI). The pencil-and-paper questionnaire, which was modified by Snowdon (1980) from the original version of Cooper & McNeil (1968), was used. It enquires about obsessional traits and symptoms, and some symptom questions incorporate a measure of the degree of interference and resistance associated with certain obsessions and compulsions.

The Fear Questionnaire (FQ) (Marks & Mathews, 1979). This self-rating questionnaire yields four scores: main phobia, global phobia, total phobia and anxiety depression. The total phobia score is comprised of agoraphobia, social and blood injury subscores.

Health Report Sheet (HRS). This is an open-ended questionnaire which we constructed for this study, and it enquires about the mental health of the respondents, their history of psychiatric morbidity and details of any treatment received.

Interviews

SADS-L. Relatives who were identified by their HRS or by a family member's account as having had noteworthy psychiatric symptoms, or who had GHQ scores greater than 4, were interviewed using the SADS-L. To check the reliability of the GHQ and HRS as screening instruments, 15 randomly selected relatives from the index and control groups who were not already being given a SADS-L interview were interviewed using this schedule: only one was found to reach 'case' status; this was a comparison-group relative suffering from alcoholism.

Standard Assessment of Personality Schedule (SAP) (Mann et al, 1981). This is a standardised interview schedule conducted with an informant relative (parent, spouse or sibling) who has an adequate knowledge of the subject. It enquires about aspects of the subject's pre-morbid personality. Its intertemporal and interinformant reliability has been shown to be satisfactory for ratings carried out on obsessive–compulsive patients years after the onset of the illness (McKeon *et al*, 1984). It deals with six personality categories based on the ICD and two further categories not covered by the ICD, these being for 'self-conscious' and 'anxious' personalities. Each personality category is rated as follows: grade 0, no features; grade 1, features present; grade 2, features pronounced (or abnormal personality). Index and comparison-group probands had their personalities rated using this schedule.

All SAP and SADS-L interviews were conducted by one interviewer (P. McK.). The SADS-L ratings were not made blindly. SAP interviews were scored blindly by Dr A. Mann.

Characteristics of the relatives

There were 61 parents, 75 sibs and 21 children in the obsessive–compulsive group and 72 parents, 74 sibs and 15 children in the comparison group. There were no significant differences between the two groups in sex ratio, age–sex distribution or marital status. The only statistically significant difference was for socio-economic class (SEC), where 16% of the index relatives belonged to SEC IV compared with 4% of the comparison-group relatives. There were on average per family 0.42 and 0.30 children over the age of 16 years for the index and comparison-group probands respectively. Family size was comparable for both groups, with the patient probands having a mean sibship size of 2.40 and the comparison-group probands a mean of 2.48.

Response patterns

In all, 88% of the patients' relatives and 83% of the comparison-group relatives returned a completed GHQ questionnaire. There was no statistically significant difference in the response rates between proband and control relatives as a whole for the GHQ, LOI or HRS (McKeon, 1983). In addition, the response rates for corresponding relatives in both groups (e.g. fathers *v.* fathers) were comparable. As regards those who failed to return the GHQ and HRS, in the case of 9% of the probands' relatives and 14% of the controls' relatives adequate information on their mental health was gleaned from two or more informant relatives.

Results

GHQ scores and history of psychiatric morbidity and treatment

There were 20% of the index relatives identified as possible 'cases', in that they had a score in excess of 4 on the GHQ, compared with 13% of the comparison-group relatives (Table I). Information from HRS and informant relatives indicating a history of psychiatric morbidity is detailed in Table I. The table does not include information gathered at SADS-L interviews. The number who had attended a general practitioner and/or a psychiatrist with psychological symptoms was significantly greater among index probands' relatives than among comparison-group relatives.

When the case-notes of relatives attending psychiatrists both as in-patients and as out-patients were reviewed, a greater number of index relatives were diagnosed as having neurotic depression, phobic neurosis, and depression or manic–depressive illness. Perhaps surprisingly, one case of obsessive–compulsive neurosis was encountered in each group of relatives (Table II).

Prevalence of mental illness based on SADS-L interviews

The reasons why potential 'cases' were given a SADS-L interview are set out in Table III.

The prevalence of mental illness detected at SADS-L interview (Table IV) clearly indicates a statistically significant excess of psychiatric morbidity among the index relatives compared with the comparison-group relatives. This excess is predominantly a reflection of a higher prevalence of neurotic disorders of the anxious, phobic and depressive types. The prevalence of obsessive–compulsive neurosis was similar in both groups of relatives.

So far all the data refer to multiple diagnoses. Enumerating individuals with one or more diagnoses shows that there were 41 cases among the index relatives compared with 21 among the comparison-group relatives (χ^2 8.3, d.f. 1, $P<0.01$).

SAP ratings

Forty-three of the obsessive–compulsive probands had their personalities rated with the SAP; the remaining seven either had no relative to act as informant (four) or had the onset of illness in childhood (three), and so could not have their personalities reliably rated with the SAP.

Personality assessments for the obsessive–compulsive probands showed a high frequency of abnormal personality traits in the obsessional, self-conscious and anxious categories, some two-thirds of these having a grade 1 or 2 score on the SAP obsessional category. The 'overall' personality grade (Fig. 1) refers to the rating irrespective of personality type: probands designated grade 2 personality category had at least one score of grade 2 on any of the three frequently occurring personality categories, those designated grade 1 had one or more grade 1 scores and those in grade 0 had no abnormal personality traits. When the overall personality grades for the index probands were plotted against the prevalence of psychiatric morbidity among their first-degree relatives, it was clear that the rate of family psychiatric morbidity was greater for those probands with grade 2 abnormal personality ratings (Fig. 1). However, neither χ^2 analysis of the data on which the figure is based (χ^2 4.8, d.f. 2, $0.10>P>0.05$) nor the correlation coefficients between the different personality categories and the familial rates of mental illness were statistically significant.

Index ($n=130$)	8.1±0.5	12.8±1.5	3.2±1.0	1.4±0.9
Control ($n=127$)	7.8±0.5	12.7±1.4	3.8±1.7	1.3±1.1

*Unpaired t-test significant at $P<0.001$.

LOI scores

LOI trait, symptom, resistance and interference scores were, as expected, significantly higher for the index probands than for those in the comparison group (Table V). The differences between the scores of index and comparison-group relatives and between the respective relatives for all of the LOI scales did not differ significantly except for the LOI trait score between mothers, with the comparison-group mothers having a higher mean.

Examination of the correlation coefficients between probands and their relatives for mean trait and symptom scores produced few significant results. Within the index group the correlations between index probands and mothers, sisters and sons were positive and high, in contrast to the low positive or negative correlations between index probands and fathers and brothers (McKeon, 1983).

FQ scores

The index relatives' mean scores for agoraphobia, social and global phobia subsections, and their total fear score, were higher than those of the comparison group. However, the differences both between index and control relatives and between respective relatives were not statistically significant.

Birth-order effect

Sixty-six per cent of the males and 56% of the females were first-born or only children, and the later-born/first-born ratio was 0.75 for males and 1.4 for females, suggesting a birth-order difference between the sexes.

As the probands were matched for birth order, the only method of studying the effect of birth order on obsessional symptoms was to compare the LOI symptom scores for first-born (excluding only children) and later-born subjects. The LOI symptom scores for the index probands and their siblings in respect of birth order was as follows: for males, the first-born had a score of 13.7 and those later-born a mean of 10.2 (difference $0.05<P<0.10$) and for females the scores were 16.0 and 14.6 respectively (difference not statistically significant).

The relationship between birth order and rate of family psychiatric morbidity showed that later-borns, both males and females, tended to have more family morbidity. When only-children, first-born and later-born categories were used to examine the relationship between birth order and level of family morbidity, a correlation of +0.35 (NS) was obtained using Goodman's and Kruskal's G (Kendall & Stuart, 1966). G is similar to other non-parametric correlation coefficient formulae, but differs in that it can be used where there are a limited number of ranks, and its applicability in small-sample experiments has been verified.

Discussion

This study showed that the first-degree relatives of obsessive–compulsive patients had a significantly higher rate of lifetime psychiatric morbidity than the relatives of non-psychiatric controls, but that this excess morbidity did not extend to obsessive–compulsive neurosis itself. General Health Questionnaire scores, self- and informant reports of psychiatric morbidity and hospital diagnoses all concurred with the clinical findings of the SADS-L interview, on which the final case count was made. In addition, the similar obsessional trait and symptom scores for the index and control families were in keeping with the clinical results.

There seems to be little doubt that the relatives of index and control probands were comparable on all the important biographical variables. The proportion of relatives in each group completing the various screening instruments, having a SADS-L interview and returning completed questionnaires were comparable. Results from the SADS-L interviews, conducted to assess the reliability of the GHQ, and data on the false positives encountered indicate that as a screening instrument the GHQ was both sensitive and specific. A potential source of bias in this investigation was the absence of blind assessment for the SADS-L interviews, but the inclusion of objective measures such as GHQ, LOI and hospital diagnoses produced useful checks.

Our exclusion of controls who were shown as definite 'cases' by SADS-L requires comment. As the primary aim of this study was to measure the familial rate of clinical and psychometric obsessionality, we considered it essential to screen potential controls for obsessive–compulsive neurosis and affective disorders because of the complex relationship between obsessions and depression and the possibility of a low rate of familial aggregation of obsessional neurosis (Rosenberg, 1967). The fact that the index controls and their relatives had obsessionality scores similar to other normative data justifies this approach (Kelleher, 1972). While the difference in the rates of mental illness between the index and control relatives is possibly magnified by our strict selection of controls, it would seem preferable to have well defined criteria, rather than employ general medical or surgical controls with varying degrees of psychiatric morbidity.

Theoretically, the unexpected finding of obsessional symptoms scores being similar for both groups of relatives might be explained by a tendency of the index relatives to underscore on the LOI, and so present themselves in a socially desirable manner. This is an unlikely explanation, as index relatives scored higher than comparison-group relatives on the GHQ and several sections of the FQ, and reliably reported details of their current and previous mental health. Furthermore, the mean LOI symptom scores for index and comparison-group relatives of 12.8 and 12.7 respectively do not differ significantly from those reported by other investigators; an analysis of 202 normal English subjects produced a mean symptom score of 12.3 (Cooper & McNeil, 1968; Kelleher, 1972).

While the higher prevalence of mental illness detected among the index probands' relatives in this study concurs with other obsessional family studies (Brown, 1942; Rudin, 1953; Greer & Cawley, 1966; Rosenberg, 1967), the low rate for obsessive–compulsive neurosis (0.7%) detected among the parents and siblings contrasts markedly with the findings of Brown (7.3%) and Rudin (3.2%). However, Rosenberg reported a prevalence rate of 0.4%, which is in keeping with the finding in this study. How are these different rates to be explained? The most likely explanation is that the different diagnostic criteria used to define 'case' status account for the disparity: both Brown and Rudin employed less stringent criteria than those of the Research Diagnostic Criteria, while Rosenberg relied in the main on hospital case-notes, compiled presumably by less biased observers.

The correlation coefficients for obsessional symptoms between probands and their relatives did not reach statistical significance, but it is interesting to note that the correlations of +0.32 between index probands and their mothers is comparable with the correlation between a small group of monozygotic obsessional twins (McKeon, 1983). In a study of five monozygotic and five dizygotic twin pairs, where one of each pair had been diagnosed as having obsessive–compulsive neurosis, the correlation coefficient for obsessional symptoms on the LOI was 0.39 for the MZ twins and 0.07 for the DZ pairs. While the higher correlation between MZ pairs might suggest that genetic factors are of prime importance, it must be weighed against a similar correlation between the index probands and mothers in the present study.

In the same twin study, the mean difference between twins on the Eysenck Personality Inventory neuroticism scale was greater for the DZ than the MZ pairs, and the DZ/MZ ratio for these differences was 1.5, compared with a similarly calculated ratio of 1.4 for LOI symptoms scores. While the numbers involved are too small to allow firm conclusions to be drawn, these results suggest that neuroticism is as likely as obsessionality to be the inherited factor.

Snowdon's (1979) finding of a birth-order effect for male obsessive–compulsive patients was here confirmed, with a hint of a similar effect being present for females. The association between birth order of the index probands and the level of familial morbidity suggests that being first-born contributed to the development of obsessive–compulsive neurosis, even in the absence of significant family psychiatric morbidity.

In conclusion, this study indicates that the prevalence of mental illness in general, and neurotic disorders in particular, is increased in families of those with obsessive–compulsive neurosis, but questions the notion that this particular disorder breeds true. Furthermore, the positive correlation between the extent of familial aggregation and the index probands' pre-morbid personalities suggests that the familial neurotic tendency may contribute to the pre-morbid personality abnormalities noted in two-thirds of the obsessive–compulsive patients. Recent obsessional twin studies (Carey & Gottesman, 1981; Torgensen, 1983) indicate that the concordance rate for neurotic disorders between MZ twins is higher than that for DZ pairs but that there is little evidence that this higher concordance applies to obsessive–compulsive neurosis. A possible interpretation of these twin studies and the results of the present investigation would be that the familial neurotic tendency is inherited, that it is manifest in a subclinical form in the subject's pre-morbid personality, and that whether or not neurotic decompensation occurs will depend on the interaction between the stressful life events and personality traits (McKeon *et al*, 1984). The form the neurotic illness may take will be influenced by factors such as birth order and early life experiences.

Acknowledgements

We would like to thank Professor Isaac Marks for his helpful comments on the design of the study, Dr Anthony Mann for scoring the SAP schedules and Dr Anthony Unwin for help with the statistical analysis. The project was supported by a research grant from St Patrick's Hospital, Dublin.

Anxiety Management for Persistent Generalised Anxiety

G. BUTLER, A. CULLINGTON, G. HIBBERT, I. KLIMES and M. GELDER

A preliminary controlled investigation of the effectiveness of Anxiety Management as a treatment for generalised anxiety disorder (GAD) is described. Patients with a primary diagnosis of GAD, in which the current episode had lasted for at least 6 months but not more than 2 years, were included. Anxiety Management, a self-help treatment including procedures for managing somatic and cognitive symptoms, and for dealing with avoidance and low self-confidence, was given either immediately or after a 12-week waiting period. The average length of treatment was 8.7 sessions. Highly significant changes in anxiety, depression, and problem ratings were shown after treatment. These changes were replicated when the waiting list group had also received treatment, and gains were maintained by both groups for 6 months. Similar degrees of improvement and maintenance of change were shown in subgroups with and without minor depressive disorder or recurrent panic attacks.

It is now generally agreed that anxiety disorders should not be treated for long periods with anxiolytic drugs because of their doubtful efficacy and because tolerance to and dependency on the drugs may develop (e.g. Tyrer & Owen, 1984; Catalan & Gath, 1985). Although about two-thirds of general-practice patients with minor affective disorders, mostly anxiety states, recover within 6 months, the remaining third remain unwell for some time (Catalan *et al*, 1984). There is a need therefore for a simple effective psychological treatment for cases which do not recover rapidly. This treatment should be of a kind that can be provided within the resources of the National Health Service. Relaxation is widely taught, but although the procedure has been shown to have a significant short-term anxiolytic effect (Mathews & Gelder, 1969), it has not been shown to have substantial long-term effects in anxiety disorders; indeed the clinical impression is that long-term effects are not impressive. This may be because patients do not practise persistently (Hoelsher *et al*, 1984), or because relaxation training fails to deal with two components of the anxiety syndrome which appear to be of particular importance: cognitions and avoidance behaviour.

Beck *et al* (1974) showed that patients with anxiety disorders have characteristic cognitions concerning personal danger. In generalised anxiety neurosis these thoughts most frequently concern loss of self-control, inability to cope, illness and social embarassment (Hibbert, 1984). Such fears are usually recognised by the patient to be exaggerated or irrational (Rapee, 1985). Two kinds of treatment have been devised to deal with these cognitions: Anxiety Management Training (Suinn & Richardson, 1971) focuses on patients' fears of being unable to cope; Beck's cognitive therapy (Beck *et al*, 1985) makes a more ambitious attempt to alter patients' ways of thinking.

In Anxiety Management Training, fears of being unable to cope are allayed by teaching ways of coping with symptoms of anxiety. This method combines relaxation, reassuring 'self talk', and practice in the use of anxiety-provoking imagery to induce anxiety, which is then brought under control by the use of reassuring imagery ('image switching'). A clinical trial of this method for patients with persistent anxiety neurosis (Jannoun *et al*, 1982) demonstrated a moderately large therapeutic effect, which persisted during 3 months' follow-up. A small number of studies has been reported of other methods of changing cognitions, although all but one was uncontrolled (Barlow *et al*, 1984; Clark, 1986; Ost, 1985; Waddell *et al*, 1984; Woodward & Jones, 1980). The results were similar to those obtained with Anxiety Management Training.

Patients in the study of Jannoun *et al* (1982) reported that image switching was difficult to carry out. Moreover further (unpublished) work of our own showed that although patients with generalised anxiety disorders do not have the 'focused' pattern of avoidance seen in phobic states, they often show partial avoidance of a large number of different situations. We therefore removed image switching from the treatment and added exposure, to deal with the avoidance behaviour. At the same time we modified the cognitive component of the treatment to place more emphasis on the identification of and response to each person's specific thoughts, rather than drawing on a common set of thoughts, or single strategy, for all patients. We called the new treatment Anxiety Management. It was presented to patients with a rationale designed to mobilise their existing resources for coping with anxiety. Information was included about the nature of anxiety and about each of the component techniques, namely those for controlling symptoms, bringing about exposure and building confidence. An earlier version of this treatment has already been shown to be a useful addition to exposure in the treatment of social phobia (Butler *et al*, 1984). The main aim of the study reported here was to carry out a controlled evaluation of Anxiety Management.

Method

Patients

Forty-five patients with generalised anxiety disorder (GAD) as defined by the Research Diagnostic Criteria (Spitzer *et al*, 1978) entered the study. Patients meeting the criteria for panic disorder as well as GAD were included provided that GAD was the primary disorder. In addition, patients were included only if the anxiety reached 7 or more on the Leeds Anxiety Scale (Snaith *et al*, 1976), and if the current episode had persisted for at least 6 months.

Patients were excluded from the study if their symptoms met Research Diagnostic Criteria for phobic, obsessive–compulsive or major depressive disorder, or if the disorder was so chronic that there had been no period of one month in the last 2 years during which they were free from symptoms. Patients who reported recurrent but discrete episodes of GAD were included. The inter-rater reliability of the diagnostic and inclusion criteria was checked by a second psychiatrist, who rated a consecutive series of ten patients on the same occasion as the assessor; the two assessors agreed about the application of these criteria in all but one case. Successive referrals were accepted until 45 suitable patients had entered the study. They were randomly allocated to one of two groups and to one of three therapists. Three patients were replaced because they had attended only two treatment sessions after one month.

Therapists

Three clinical psychologists, each with extensive experience in the psychological treatment of anxiety disorders, treated equal numbers of patients. Before the trial the therapists completed a training period, using an instruction manual, during which they developed a consistent approach to therapy. During the trial each therapist tape-recorded a sample of therapy sessions. Regular meetings were held, to discuss issues arising during treatment, and to help maintain a consistent approach to therapy throughout the study.

Procedure

Patients were referred to the study either directly by their general practitioners or from psychiatric out-patient clinics. An independent assessor interviewed the patients, made the diagnosis and assessed the patients' progress. The assessor did not know which therapist was treating each patient or whether the patient was in active treatment or on the waiting list. Suitable patients were randomly allocated to immediate treatment with Anxiety Management (AM), or to a waiting list (WL). Patients in the WL group entered treatment after 3 months. Treatment was given individually, and consisted of between four and twelve sessions, according to the patient's need (see below), each session lasting not more than one hour. Booster sessions were given 2 weeks and 6 weeks after the end of treatment. A post-treatment assessment was carried out 3 months after the start of treatment, and follow-up assessments were conducted 3 months and 6 months later. The first and last of these assessments were carried out by the independent assessor, and the 3-month follow-up assessment was completed by the therapist. Some patients were seen at the hospital, some in health centres.

Treatment

Treatment was described in a booklet which was given to patients shortly before their first therapy session. The treatment was presented as a form of self-help designed to mobilise the patient's own resources for managing symptoms of anxiety. The booklet starts with information about the nature of anxiety and its common manifestations, and contains questions which require the patient to apply the ideas in the booklet to his or her own difficulties. The account emphasises that it is normal to feel anxious at times, and that anxiety becomes a problem only when it does not subside appropriately. The booklet goes on to suggest that patients should seek out maintaining factors and try to eliminate them. Maintaining factors include anticipatory anxiety, fear of fear, avoidance, and loss of self-confidence. Specific techniques are then described to counteract each of these maintaining factors. Anticipatory anxiety and fear of fear are counteracted by learning to control symptoms with relaxation, distraction, and the control of upsetting thoughts. The latter involves identifying thoughts and images that provoke, maintain, or exacerbate anxiety, examining them to find out how realistic they are and whether there are more helpful or more realistic ways of thinking, and devising practice tasks to test the thoughts. Avoidance is reduced by using graded practice. Self-confidence is increased by identifying the person's strong points, by engaging in rewarding and pleasurable activities, and by paying attention to aspects of life in which the person is functioning relatively well. Copies of the booklet are available from the first author.

Throughout treatment, patients were encouraged to play an active role by setting their own goals, deciding which techniques would be appropriate for them, planning homework assignments and monitoring anxiety. Tape-recorded instructions for progressive muscular relaxation were provided at the first session. The exercises were practised with the therapist as well as at home if either the patient or the therapist thought this would be helpful. Techniques for controlling symptoms were introduced one at a time, and practised both separately and while graded practice and activities to increase confidence were being carried out. All patients were encouraged to reduce their consumption of anxiolytic medication.

Patients could stop treatment after a minimum of four sessions provided that they were no longer distressed by symptoms of anxiety, their anxiety ratings had been stable for at least 2 weeks, and the therapist shared the patient's confidence that he or she could control symptoms. During the booster sessions, strategies for managing anxiety were reviewed and the patient was prepared for dealing with future fluctuations in anxiety, or other setbacks.

Measures

Mood ratings

The assessor rated both anxiety and depression with the Hamilton Scales (Hamilton, 1959, 1967) and with the 9-point rating scale developed by Watson & Marks (1971). Patients rated anxiety and depression with the Leeds Scales (Snaith *et al*, 1976) and the 9-point rating scale. They also completed the State–Trait Anxiety Inventory (STAI; Spielberger *et al*, 1970).

Expectations

Expectations about the outcome of treatment were rated by patients on a 0–8 scale after reading the booklet, and again 4 weeks later. Patients also rated the suitability of treatment on a 0–8 scale before and after treatment.

Background and descriptive data

The assessor completed the Present State Examination (PSE; Wing *et al*, 1974) at the first assessment and at 6-month follow-up. Patients completed the General Health Questionnaire (GHQ; Goldberg & Hillier, 1979) at each assessment, and also rated the severity and degree of interference with their lives of the three problems that they found most troubling. These were identified with the help of the assessor, and rated on a 0–3 scale.

At the first interview the assessor completed a structured interview designed to collect information about situational anxiety, avoidance, anticipatory anxiety, and the presence of anxiety-related thoughts. He also completed the Life Events Checklist (Paykel *et al*, 1969) and the Index of Social Support (Surtees, 1980). Findings related to these measures are presented in Butler & Gelder (1987).

Within-treatment measures

Patients rated anxiety (0–8) at every therapy session, and completed the Leeds Scales at the fourth session. At each session, therapists recorded the amount of medication taken since the last session, the number of reported panic attacks, the length of the session, techniques discussed and homework set.

Statistical analysis

Initial differences between the groups and change within-groups were analysed with *t* tests. Between-group differences were tested with analysis of covariance, taking the score on the first occasion of assessment as the covariate. Repeated-measures analysis of variance was used to analyse changes within the WL group over the first three assessments: assessment one, pre-treatment and post-treatment. Multivariate analysis of variance was used to evaluate the response to treatment of different subgroups.

Results

Patients

There were 144 patients referred to the study. Of these, 81 failed to meet the inclusion criteria: 28 had anxiety which was too mild, or too short a history; 12 had too long a history; 21 were phobics (14 of whom were agoraphobic); 10 met the criteria of major depressive disorder; and 10 had various other disorders. Of the remaining 63, 18 did not or could not attend, or preferred other treatment. Thus 45 patients (29 females and 16 males) entered the study. The average age was 37.4 years (range 20–57). The average school-leaving age was 16.3 years (range 15–19). Thirty-six patients were married, five single and four divorced or separated. Of all the patients, 82% were rated as cases according to the PSE at the time when they were accepted into the study. Using the PSE definition of panic attacks, 13 patients fulfilled the criteria for panic disorder.

There were 22 patients in the AM group, and 23 in the WL group. About half the patients were treated at health centres, and the rest at out-patient clinics. Three patients in the WL group did not receive treatment after the waiting period. Of these, two had to be withdrawn because they became significantly more depressed during the waiting period, and a third refused treatment because he had improved; a fourth patient finished treatment but declined to complete any further assessments. Therefore post-treatment ratings are available from only 19 patients in the WL group. At the end of the follow-up period one patient could not be traced and a further two, one in each group, had to be excluded because they had received antidepressant medication during the interval since treatment had ended. Thus at 6-month follow-up the total sample consisted of 38 patients, 20 in the AM group and 18 in the WL group.

There was no significant difference between the ages of the two groups (Table I). There were 14 women and 8 men in the AM group, and 15 women and 8 men in the WL group. Before treatment (Table I) there were no differences between the groups on any of the main measures, including the Leeds and Hamilton scales, the 0–8 ratings of both anxiety and depression, the STAI ratings of state and trait anxiety, and the GHQ ($P > 0.10$ in every case).

Expectations of improvement, rated by both patients and therapists, were moderately high before treatment started (mean = 5.49 on the 0–8 scale), and remained at this level when re-rated at the fourth session. Similarly, initial ratings of treatment suitability were moderately high (mean = 5.47 on the 0–8 scale), and did not change after treatment. Neither of these ratings differed significantly between groups or between occasions. There were no differences in response to treatment according to therapist or sex of patient, and these variables will not therefore be discussed further.

TABLE I
Main outcome measures: mean values

	Assessment 1		*After wait*	*After treatment*		*6-month follow-up*	
	AM[1] (*n*=22)	*WL*[2] (*n*=23)	*WL* (*n*=23)	*AM* (*n*=22)	*WL* (*n*=19)	*AM* (*n*=20)	*WL* (*n*=18)

Interference	1.7	1.4	1.5	0.8	0.7	0.7	0.7

1. AM = Anxiety Management.
2. WL = waiting list.

Main between-group comparison

The pattern of changes over the whole period of the study is shown in Fig. 1, and the mean outcome measures for the main occasions of rating are shown in Table I. Data from the first two assessments were used for this analysis. In the interval between these assessments the AM group had completed treatment and the WL group had completed the waiting period.

For all the main measures, the scores of the two groups differed significantly at the second assessment ($P<0.001$ in every case). The AM group changed significantly on every measure ($P<0.001$). The WL group did not change significantly on eight of the nine measures of mood. Only the depression ratings of the Hamilton Rating Scale were significantly less after than before the waiting period, ($t=2.52$, d.f. 22, $P<0.05$).

Changes in the WL group after treatment

Data from the WL group alone were subjected to repeated-measures ANOVA for the first three occasions of assessment (occasion one, pre-treatment and post-treatment). This analysis showed a main effect of occasions on every measure ($P<0.001$). The differences between the mean scores on each occasion were then tested with Tukey tests. For eight of the nine measures, ratings did not differ between the first and second occasion (i.e. the waiting period) but they changed significantly during treatment ($P<0.01$ in every case). Despite a significant overall change in the patients' 0–8 rating of depression, neither the change during the waiting period nor that during treatment reached significance when tested separately.

Differences between groups after the WL group had received treatment

This analysis was designed to find out whether the effects of treatment in the AM group were replicated in the WL group when it subsequently received treatment. Between-group differences were tested with ANCOVA, using data from the first assessment as the covariate for both groups. On eight of the nine measures there were no differences between the groups after both had received treatment. On the ninth measure, the patients' 0–8 rating of depression, the WL group had significantly higher scores than the AM group ($F=5.57$, d.f. 1, 38, $P<0.05$). Patients in the AM group received a mean of 8.9 treatment sessions compared with 8.4 for those in the WL group; this difference was not statistically significant.

Analysis of the problem ratings was conducted in the same way as the analysis of mood ratings (mean scores are included in Table I). During treatment these ratings decreased significantly in both groups.

Maintenance of change

In the AM group, improvement was maintained during follow-up on eight of the nine measures of mood, and on the problem ratings. A significant further improvement was detected in ratings of the Leeds Anxiety Scale ($t=2.11$, d.f. 18, $P<0.05$). In the WL group, improvement was

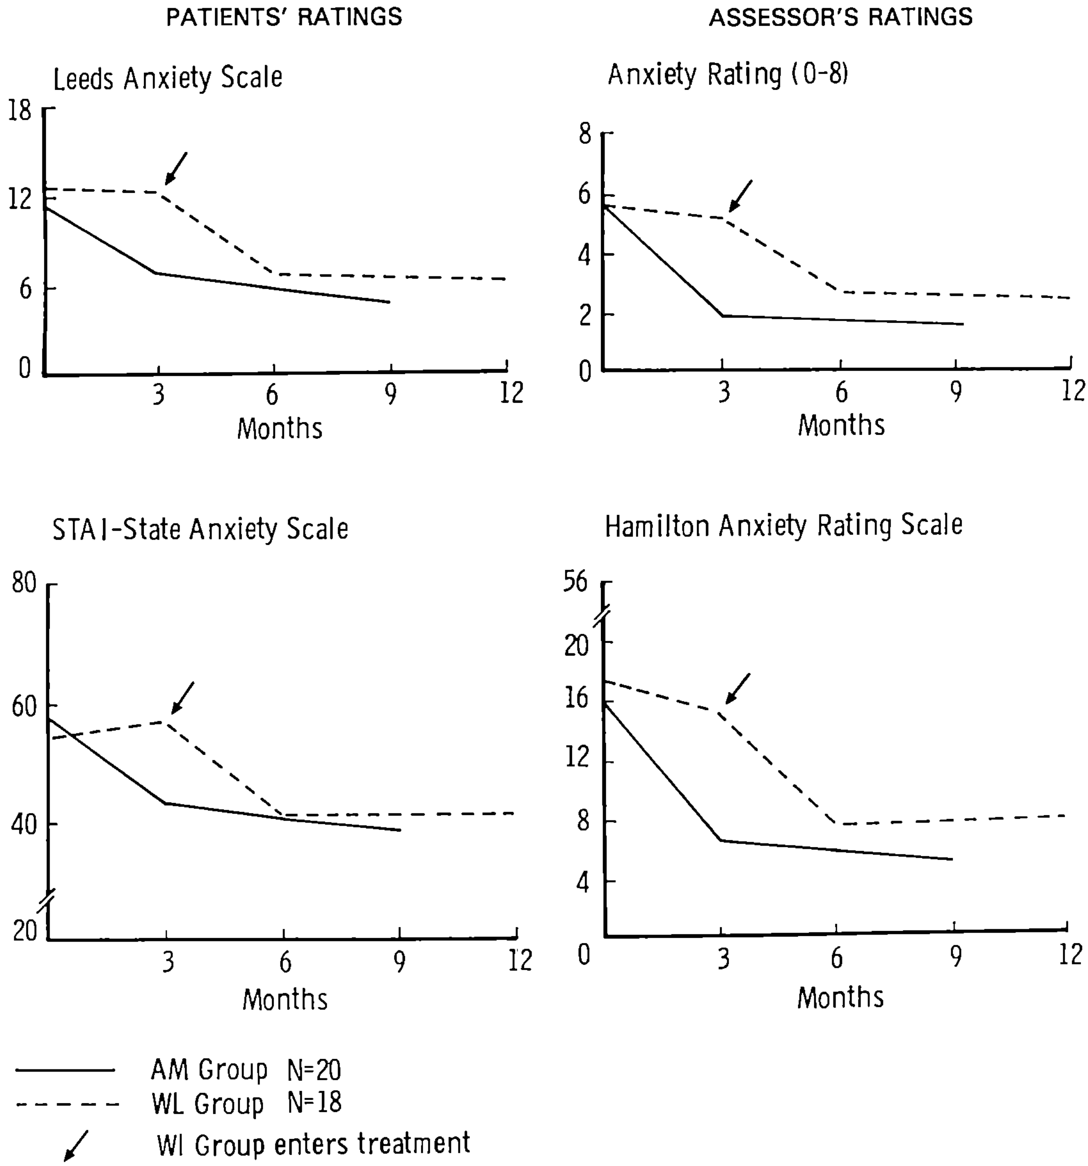

FIG. 1 The pattern of changes in measures of anxiety during the whole period of the study ($n = 38$).

maintained on every measure during follow-up. At the 6-month follow-up the groups did not differ significantly on any of the measures.

Summary of comparisons and changes

In summary, there were no differences between the groups either at the initial assessments or after the WL group had completed the waiting period. Both groups improved significantly with treatment. The groups did not differ significantly after treatment or at follow-up on any of the measures of anxiety. For this reason, in subsequent analyses data from both groups were combined wherever appropriate.

Other indices of improvement

By the end of treatment the scores of 21 patients (51%) fell below the cut-off between patient and non-patient populations on the Leeds Scales. By the end of follow-up 24 patients met this criterion, and at this time only 8 patients were still diagnosed as cases according to the PSE (mean total scores were 16.2 at the start of the study and 4.9 at the end). Mean scores on the GHQ for the whole group were 25.7 before treatment, 7.6 after treatment and 7.6 at 6-month follow-up. Initial scores on the STAI-trait anxiety scale at assessment one and 6-month follow-up are shown in Table I; on neither occasion was the difference between the groups significant.

Additional information was collected from general-practice records after the trial had ended. The 6-month follow-up period was thus extended by about a year (range 5–22 months). Records were available for 36 patients (95% of those included in the 6-month follow-up); the remaining two were untraceable. Just under two-thirds (22 patients) had had no further contact with their general practitioner because of anxiety. A further five patients had consulted their general practitioner occasionally because of anxiety (mean = 1.8 times). Two of these were reassured after discussion, and three were given anxiolytic medication to help with particular stresses; for example, examinations. The remaining nine patients, a quarter of the sample, had received more extensive treatment for anxiety, including taking regular anxiolytic medication for at least part of the follow-up period. Seven of these had also received antidepressant medication. Despite additional treatment, only two of these nine patients were reported as improved.

Changes in the use of medication

At the start of the study, 46% of the patients were taking regular medication. Of the prescriptions, 73% were for anxiolytics, 14% for hypnotics, and the remainder for antidepressants and combined preparations. During the waiting period three patients started to take regular medication and two ceased to do so. There was no difference between the groups in frequency of drug use. After treatment 16% of the patients were still taking regular medication but had decreased the dose. Six months later this had fallen to 13%. Two patients, 10% of those originally taking regular medication, failed to reduce their medication throughout the study.

Comparison of patients with and without minor depressive disorder

The group was then divided according to whether or not they had fulfilled the criteria for minor depressive disorder at the start of the study. The 18 patients (44%) with minor depressive disorder as well as GAD were compared with the 23 who had GAD alone. These two subgroups did not differ in age, or in the mean number of treatment sessions (depressed 9.0, non-depressed 8.5). Although 81% of the depressed and only 50% of the non-depressed patients were women, this difference was not significant. Multivariate analysis of variance, using data from the main measures at the first assessment showed that the depressed patients had more severe symptoms than the non-depressed patients at the start of the study ($F=5.79$, d.f. 9, 31, $P<0.001$). Multivariate analysis with repeated measures showed a highly significant main effect of time ($F=78.9$, d.f. 2, 35, $P<0.001$). Both subgroups improved during treatment and maintained this improvement during the follow-up period. There was no main effect of depression, but a significant time × depression interaction ($P<0.02$) indicated that the depressed patients tended to improve more during treatment, and hence no longer differed from those who were not depressed either immediately after treatment or at 6-month follow-up.

Comparison of patients with and without panic attacks

At the time of the first assessment, 21 (47%) of the 45 patients had recurrent panic attacks (i.e. at least one every 3 months), and 19 (42%) had never had a panic attack. (Panic attacks were defined as in the PSE.) Five patients (11%) had had rare, isolated attacks. In the WL group, 9 patients (39%) reported having recurrent panic attacks at both the first and the second assessment, and there was no significant difference between the estimated weekly frequency of attacks on the two occasions. Twenty of the 41 patients treated had recurrent panics. Their mean attack frequency was 1.76 per week before treatment, 0.23 after treatment and 0.10 at 6-month follow-up; by this time attacks were generally occurring so seldom that it was difficult to estimate their frequency accurately. However, of the 20 patients who had recurrent attacks at the start, 14 (70%) reported that they had had no attacks for a period of at least 3 months. The frequency of panic attacks before treatment and at 6-month follow-up is shown in Table II.

TABLE II
Panic attack frequency before treatment and at 6-month follow-up

	Pre-treatment (%)	*6-month follow-up (%)*
⩾1 a week	65	0
⩾1 a month	25	20
<1 a month	10	10
0 in 3 months	0	70

In order to compare the response to treatment of those with and those without recurrent panic attacks, the AM and WL groups were combined, omitting the five patients who had rare panic attacks. As noted above there were 20 patients in the panic attack group and 16 in the panic-free group when treatment began. At 6-month follow-up the two groups comprised 18 and 15 patients respectively. Comparison of these two groups using multivariate analyses shows that the patients with panic attacks tended to have marginally ($P=0.07$) more severe symptoms at the start of the study. Treatment effects were highly significant and similar in both groups, and the improvement during treatment was maintained during follow-up. There was no difference between the groups on any subsequent occasion.

Comparison of patients receiving shorter and longer treatment

In order to find out whether the patients who required the shortest period of treatment could be identified at the start of the study, the whole sample was also grouped according to length of treatment. When the group was divided at the mean number of sessions (8.7), there were 20 patients in the short treatment group (mean 6.3 sessions) and 21 in the long treatment group (mean 11.0 sessions). At the 6-month follow-up there were 18 and 20 patients in the two subgroups. The multivariate analyses showed that those who had longer treatment started with more severe symptoms. There were main effects of both time and treatment length, without any interaction between these factors, showing that both groups improved to the same extent, and maintained this improvement during follow-up.

Discussion

The main aim of this study was to find out whether Anxiety Management is an effective treatment for generalised anxiety. The findings presented here show that patients with GAD treated with Anxiety Management changed more than a matched group waiting for treatment. The changes during treatment were highly significant, and were replicated almost exactly when patients in the waiting list group completed treatment. In both cases the effects of treatment persisted throughout the 6-months follow-up. By the end of the study the anxiety ratings of half the patients had fallen below the cut-off point that distinguishes a normal from a clinical population on the Leeds Anxiety Scale. The improvement was shown in measures of depression and of patients' problems, as well as in measures of anxiety. We cannot say how far our population after treatment differs from the normal population because the relevant norms are not available. Nevertheless, it seems reasonable to conclude that Anxiety Management has a substantial effect. An appropriately designed comparative treatment trial will have to be carried out in order to ascertain the specificity of the treatment, and to identify its most effective parts.

Particular care was taken to ensure that the diagnosis of generalised anxiety disorder was reliable, and to exclude phobic patients with generalised anxiety for whom exposure might have been the treatment of choice. The group was homogenous, in so far as only those with anxiety that had persisted for at least 6 months were included. Patients with more chronic disorders were excluded because they are difficult to distinguish from those with personality disorders, and because many complain of depression as well as anxiety. We excluded those chronic patients whose symptoms had been continuously present for 2 years. However, some of those included had had previous discrete episodes of anxiety and had high trait anxiety scores; they might therefore fulfil less stringent criteria for chronicity. Our results cannot be taken to apply to patients with more chronic anxiety, and this group requires further study.

It might be supposed that patients who are depressed and anxious would respond less well than those with anxiety alone. In these cases depression might be the primary disorder, despite the presenting complaint of anxiety; Anxiety Management might not help overcome coexisting depression or depression might reduce the vigour with which patients would carry out Anxiety Management procedures. In keeping with this idea, there is some evidence from this study that the initial level of depression is important. Thus, two patients had to be withdrawn from the study because they became significantly more depressed during the waiting period and urgently required other treatment. Two others continued to ask for help for depression during the follow-up period, and received antidepressant medication. The remaining patients were about equally divided between those who were only anxious and those who were anxious and fulfilled the criteria for minor depressive disorder (i.e. depressed mood persistent for a minimum of 2 weeks, and at least two symptoms from a checklist of 16). These two subgroups were not significantly different after treatment or at follow-up, suggesting that Anxiety Management is effective in both kinds of case.

About half of our patients had recurrent (though not very frequent) panic attacks. The frequency of attacks declined substantially with treatment, and there was no difference between subgroups with and without panic attacks either in their immediate response to treatment, or in the maintenance of change. This may be because lowering the level of general anxiety makes panic attacks less likely. This would be the case if panic attacks are merely an index of severity of anxiety, rather than an indication of a distinct form of anxiety disorder. It may also be because Anxiety Management, which contained instructions on how to manage panic attacks, helped patients to re-evaluate the significance of the symptoms they experienced during attacks, and helped them to control these symptoms, perhaps by reducing their fear of possible catastrophic consequences.

Even though it is not yet known which components of Anxiety Management are effective, this brief and simple treatment is clearly suitable for patients with persistent generalised anxiety disorder, who are commonly seen in general practice and for whom prolonged drug treatment is unsatisfactory. Cognitive therapy (Beck *et al*, 1985) and combinations of relaxation and cognitive treatment (e.g. Barlow *et al*, 1984) have also been proposed for anxiety disorders, but they have not yet been evaluated in controlled trials. These treatments may be more complex and in most cases last longer than Anxiety Management, which requires about half as much therapist time as the treatment described by Barlow *et al.* Anxiety Management is easily taught to therapists, and readily understood by patients. It is also a rational method of treating generalised anxiety disorders because, as well as including procedures for controlling symptoms, it deals with anxious cognitions and avoidance behaviour, both of which appear to contribute to the maintenance of anxiety disorders.

Acknowledgements

This research was supported by the Medical Research Council of Great Britain. We are indebted to the many general practitioners who referred patients to the study, and to the patients who completed so many assessment procedures during the course of treatment. We would like to thank J. Catalan, D. Clark and P. Cowen for their comments on an earlier draft of the manuscript.

Suicide Following Parasuicide in Singapore

W. F. TSOI and E. H. KUA

Suicide was attempted by 1641 people (502 males and 1139 females) in Singapore during 1980. Eleven of these committed suicide during the following three years, giving a suicide rate of 0.67%. Of the eleven suicides, five had schizophrenia and three depression. The risk of suicide in the year following attempted suicide is lower in Singapore (0.5%) than in Britain (1.6%). High risk factors for the Singapore patients were being Chinese, being male, and having a mental illness.

Singapore is an island republic of 610 km^2. In 1980 it had a population of 2.4 million, comprising Chinese (77%), Malays (15%), Indians (6%), and other ethnic groups (2%). The aim of this study was to find out how many patients who attempted suicide in 1980 died of suicide during the following three years. This may throw some light on those patients who are a high suicide risk.

A follow-up study on the fate of attempted suicides has not previously been carried out in Singapore. A study of the fate of all the attempted suicides in one year for a whole country is not easy to carry out; it is possible in Singapore because (a) it is an island with a non-mobile population, (b) it has a unique registration system, in which every Singapore resident carries only one identification number which is used both for hospital registration and death registration, and (c) almost all its attempted suicides are admitted to government general hospitals for treatment.

Suicide statistics in Singapore

The first comprehensive study of suicide in Singapore was by Murphy (1954). He analysed data from the period 1925–1952 and concluded that there had been a steady increase in the suicide rate since 1948. A subsequent study by Chia (1978) showed that over the previous 80 years the suicide rate had been about 10 per 100 000, with a peak of 15.5 per 100 000 during the period 1936–1940. The commonest method of suicide was caustic soda poisoning (43%) in 1950 (Murphy, 1954), hanging (49%) in 1961 (Chia & Tsoi, 1972), and jumping from heights in 1980 (Tsoi & Kok, 1982). The commonest predisposing causes were believed in all three studies to be mental and physical illness.

Murphy (1954) also studied attempted suicide in Singapore, and analysed 34 cases from police records. The commonest method was caustic soda ingestion (34%). Tsoi (1970) investigated 192 cases in a general hospital, and showed that household poisons such as bleaching liquids, washing detergents, and insecticides accounted for 57% of the cases. The two most recent surveys (Chia & Tsoi, 1974; Tsoi & Kok, 1981) showed that the commonest method was drug overdose (57% and 61% respectively). This shows a trend towards the use of less dangerous substances.

Method

All cases of attempted suicide admitted to the four major government general hospitals in Singapore between 1 January 1980 and 31 December 1980 were recorded. Attempted suicide, in this survey, was defined as all non-accidental self-poisoning and self-injury. This did not include a small number admitted to private hospitals or those who were treated at home or in out-patient clinics. Details of all cases of suicide between 1 January 1980 and 31 December 1982 were obtained from the records in the Coroner's Court. The Court in Singapore is based on the English legal system, and a verdict of suicide by the Coroner reflects a legal decision in which an important element is that the deceased intended to take his own life – evidence of such intent is necessary before classifying a death as suicide. If information obtained is insufficient to enable the Coroner to arrive at a decision, an open verdict is returned. During the period of study there was one Coroner. The names and identification numbers of the suicide and attempted suicide patients were matched.

Results

During 1980 1641 persons attempted suicide. Of these, 46 (2.8%) made second attempts and 12 (0.7%) made three

70+	12	44	13	35	25	39
Unknown	15	—	25	—	40	—
Total	502	41	1139	96	1641	68

or more attempts. There were 502 males and 1139 females (ratio = 1:2.3). Their distribution by ethnic group is given in Table I, and by age in Table II.

Of the 1641 attempted suicide patients, 11 (8 males and 3 females) died of suicide during the next three years (8 in the first year, 2 in the second year and 1 in the third year). The methods of suicide were jumping (6), hanging (4) and poisoning (1). They were all Chinese, and their mean age was 32.1 years (s.d. = 12.3 years), which was slightly higher than that for the attempted suicides (mean = 30.6 years, s.d. = 17.4 years). Seven (64%) suffered from mental illness (five from schizophrenia and two from depression). The data therefore showed that in Singapore only a small proportion of attempted suicides (0.67%) died of suicide during the following three years.

Discussion

The attempted suicide rate in Singapore was highest among the Indians and lowest in the Malays. The main reason for attempted suicide was relationship problems, such as the threat of separation from boyfriends or girlfriends (Tsoi & Kok, 1982). Such problems affect the Indians more because they are a minority group and the choice of marital partners within the same ethnic group is limited. The main reason for the low rate among the Malays was their Islamic religion – for Moslems, suicidal behaviour is a sin.

Follow-up studies of attempted suicides indicate that only a small percentage will subsequently commit suicide; Stengel (1971) showed that rates varied from 0.05% to 13.2%. The wide variation was due mainly to the nature of the original parasuicide samples. If the samples consisted of high risk cases such as those admitted to mental hospitals, the subsequent suicide rate would also be high. Three studies (Kessel & McCulloch, 1966; Buglass & McCulloch, 1970; Pierce, 1981) followed up unselected general hospital referrals; they found rates of 1.6% for one year, 3.3% for 3 years, and 2.9% for 5 years respectively. These studies show that the risk of subsequent suicide after attempted suicide is 3–5 times higher in Britain than in Singapore, where the rates are 0.5% after one year and 0.67% after 3 years. For the Singapore patients, high suicide risk was found to be associated with being Chinese, being male, and having a mental illness.

Can Psychiatric Nurses 'Catch' Schizophrenia?

The incidence of schizophrenia among psychiatric and general trained nurses was investigated for the period 1955–1979 in Northern Ireland. No difference was found. These results do not support the hypothesis of schizophrenia as a horizontally transmitted infectious disease.

The hypothesis that viral infection might either be the cause of or one of a number of aetiologies of schizophrenia has received greater attention in recent years. Crow (1984) and King *et al* (1985*a*) have reviewed the history of the hypothesis, which was initially suggested by the model of post-influenzal psychosis (Menninger, 1926). There are four principal suggestions as to how viruses might be involved. The most widely investigated is the possibility of a latent infection with a common virus, initiated perhaps in the perinatal period or as a result of impaired immunity (Torrey *et al*, 1978; De Lisi *et al*, 1981; King *et al*, 1985*a*,*b*). Another hypothesis, as yet only barely investigated, is of infection by uncommon viruses, such as arborviruses. A third hypothesis suggests the possibility of transmission of an unknown infective agent from schizophrenic patients to susceptible individuals (Crow, 1983*a*); and a fourth hypothesis, also proposed by Crow (1984), suggests the possibility of retroviral integration into the genome.

This study was designed to investigate the third of these hypotheses, the so-called 'contagion hypothesis'. On this hypothesis we would predict that people in close contact with schizophrenic patients would be more likely to develop the illness. Apart from family members, where the complication of genetic factors makes investigation of the hypothesis difficult, a useful group to study are psychiatric nurses. We have examined the rates of schizophrenia in psychiatric hospital nurses compared to general hospital nurses from 1955 to 1979.

Method

In Northern Ireland a computerised Central Mental Health Records Scheme (CMHRS) has been in operation since 1962. Psychiatric hospitals send details of all their hospital admissions and out-patient clinic referrals to a central office. The information provided includes simple demographic data, such as age, sex and occupation, as well as date of admission or referral, length of illness and diagnosis. The patient's name is not included. Each patient receives a Central Record (CR) number, and information relating to subsequent readmissions or re-referrals to the same hospital will be relayed to the CMHRS under the same CR number. If a patient moves to a different hospital, they should retain the same CR number because of cross-checks between hospitals when a patient declares a previous history. Some patients, however, inevitably obtain more than one CR number. Diagnostic information held on the CMHRS computer file seems fairly reliable, in our experience, for in-patients with diagnoses of psychotic illness, but is much less so for out-patients and for diagnoses of neuroses and personality disorders. We obtained the CR numbers for all those cases entered on the CMHRS whose diagnosis was, at some stage of their illness, 'schizophrenia', and whose occupation was recorded as 'nurse'.

TABLE I
Cases discarded

Nursing assistant	10
Veterinary nurse	1
Other occupation	4
Wrong diagnosis	4
Ill before nursing	2
Onset of illness after age 60 years	3
Total	24

This gave us 106 CR numbers and 96 individual 'cases'. With the consent of the individual hospital Medical Staff Committees we then traced the casenotes of all these 'cases' through each hospital's Medical Records Department. Some of the 'cases' had been referred to more than one hospital. The casenotes were examined in detail for diagnostic information (to accord with ICD-9 classification) and occupational history. We discarded 24 cases for the reasons noted in Table I. We retained only 'cases' who appeared to have been either SRN or RMN trained. Some of our so-called 'nurses' had been nursing assistants and we felt that these would not reliably be recorded as having an occupation as a 'nurse', so that quite possibly many other nursing assistants might have been diagnosed as having schizophrenia but not have appeared in our list of 'cases'.

Though the CMHRS was commenced only in 1962, all current in-patients at that time were entered. These patients, as well as many others entered on their next referral, of course, had ages of onset of illness before 1962. In order to relate the data to the respective numbers of nurses at risk, we obtained figures from the local Department of Health and Social Services for the total numbers of nurses employed in general hospitals and in psychiatric hospitals. These were available only from 1955.

TABLE II
Numbers employed, and numbers developing schizophrenia

Period	*General nurses*		*Psychiatric nurses*	
	Employed	*Falling ill*	*Employed*	*Falling ill*
1930–1939	—	2	—	0
1940–1949	—	1	—	1
1950–1954	—	3	—	1
1955–1959	3854	4	1312	0
1960–1964	5247	5	1841	1
1965–1969	7165	16	2346	4
1970–1974	8978	16	2453	6
1975–1979	13020	8	2900	4

Results

Results are shown for the final 72 'cases', of whom 52 had nursed exclusively in general hospitals and 20 had nursed in psychiatric hospitals. However, nine of the latter had apparently worked for periods in both. Of these, three had worked largely in general hospitals and appeared to have become ill before doing psychiatric nursing. These three cases' were therefore included with the 'general' nurses. The other six had worked primarily as psychiatric nurses, with only brief periods in general nursing. For the 'general' nurses (54 female, 1 male) the mean age of onset of illness was 29.8 years, and for the 'psychiatric' nurses (11 female, 6 male) it was 28.1 years. There was no statistically significant difference between these ages of onset.

Table II shows the average numbers of nurses employed in each category for quinquennia from 1955 to 1979, along with the numbers developing schizophrenia for the first time during the same periods, as well as in the period 1930–1954. These figures were then expressed as an *annual* rate per 1000 of the population of each group of nurses. Using the same formula as for comparing death rates, the two groups were compared for the period 1955–1979, but because the numbers were small the figures for the whole 25-year period were averaged. This gave an annual rate in general nurses of 0.256 per 1000 and in psychiatric nurses of 0.276 per 1000. These are not statistically significantly different. Clearly, no statistical comparison is possible for the period before 1955 as we do not have nurse employment statistics prior to this date.

Discussion

The idea of schizophrenia as a contagious, infectious disease would imply that those in close contact with schizophrenic patients would be more liable to develop the illness, and thus that psychiatric nurses should be at greater risk than general hospital nurses. The hypothesis was suggested from a synthesis of certain genetic and epidemiological data (Crow, 1983*a*), the interpretation of which was the subject of some debate (Murray & Reveley, 1983; Crow, 1983*b*). Our results clearly do not support it.

The data used can, of course, be criticised. It is possible that there might be under-reporting to the CMHRS of the occupation 'nurse' as there might be a feeling that this would prejudice a colleague in some way. However, if anything, the annual rate of new cases among both groups of nursing staff would appear to be higher than the 14 per 100 000 population per year often suggested (Gottesman & Shields, 1982). We may also have missed some of the cases of schizophrenia because they had not been diagnosed as such and therefore not recorded on the CMHRS. This error should only result in our numbers being smaller than expected (which does not seem to be the case) and in any case should affect both groups equally.

One advantage of studying nurses is that they will usually be working fairly consistently during the period of greatest risk for the onset of schizophrenia. A comparison of psychiatrists with other doctors would be of little value as they would often not begin to specialise until after a substantial part of the period of greatest risk had been lived through. What this approach does not take into account is the possibility that the schizophrenic patient might be 'infectious' before the onset of the illness, but this seems unlikely. We were unable to find any comparable data, as most previous research on psychiatric illness in health care workers has focused on anxiety, depression, stress and suicide (Denning, 1986). Study of psychiatric illness in doctors in general has not identified schizophrenia as a particular problem (Murray, 1983).

Thus, the idea of schizophrenia as an infectious disease does not really appear to have support. Indeed, in a re-analysis of the original argument, Crow (1984) also accepts this. The hypothesis also fails to explain the phenomenon of birth seasonality (Hare & Price, 1968). Furthermore, attempts to transmit an infective agent from brain tissue of schizophrenic patients to animals have so far been unsuccessful (Baker *et al*, 1983; Asher *et al*, 1984).

Acknowledgements

We thank Mr T. McLarnon (Statistics Branch, DHSS) and Mrs E. Hamill. We are also indebted to the medical staffs of Belfast City, Craigavon, Downshire, Gransha, Holywell, Newtownards, Purdysburn, St. Luke's and Tyrone and Fermanagh hospitals for permission to study their casenotes.

Paranoid Psychoses after Abuse of Proprietary Cold Remedies

It is well established that psychosis may arise in the context of the abuse of certain prescribed or illicit drugs. Two cases of paranoid psychosis are described in which proprietary preparations containing amphetamine-like drugs were abused. The role of these drugs is discussed with reference to previous case reports, and it is emphasised that initial clinical assessment and urinary screening for drugs may fail to reveal the relevant history with respect to proprietary medicines.

Abuse of proprietary cold remedies may lead to psychosis. Two cases are reported in which psychosis occurred and in which the connection with drug ingestion was not immediately evident.

Case reports

Case 1

A 55-year old man was admitted to hospital with a 6-week history of withdrawal, abnormal behaviour and paranoid delusions involving a plot to kill him. He described delusional ideas of reference and misinterpretation of commonplace events (identifying passers-by as undercover "hit men"). He had attempted to blow himself up to escape his persecutors and had tried to buy a sawn-off shotgun to protect himself. When admitted to hospital, he demonstrated widespread and systematised delusions. His speech was difficult to follow and at times was incoherent, closely resembling the speech pattern characteristic of schizophrenic thought disorder. Although at admission there was some evidence of clouding of consciousness in that he gave clearly erroneous dates of birth for his family members, this was not immediately apparent or striking and when formally examined in the psychiatric unit 7 days after admission he was fully oriented, demonstrated no cognitive abnormality, but remained floridly deluded. At this time he also described an episode of visual hallucinosis which had occurred some weeks previously. Further questioning revealed he had for 2 years taken various proprietary medicines such as kaolin and morphine, analgesics, and Collis Brown's mixture to settle his nerves, but in recent months he had had only Contac 400 capsules, in doses of ten per day, and paracetamol. A drug screen for amphetamines, barbiturates and opiates was negative. He was treated with neuroleptic medication and recovered completely over a period of 2 months. Neuroleptic medication was discontinued after 8 months, and at follow-up over 20 months he remains drug-free and free of symptoms.

Case 2

A 48-year-old policeman was admitted to a general hospital with a 12-day history of headaches and cold symptoms. Two days later he experienced complex and frightening visual hallucinations. These were experienced as real events occurring on the ward. The following day he was experiencing auditory hallucinations (including his own thoughts recorded and played over the public address system) and developed paranoid delusions about the hospital and staff. He was transferred to the psychiatric unit at this hospital where he described a plot to discredit himself and the police force, and to overthrow the government. He was hallucinating voices in the second and third persons and believed himself to be under a hypnotic influence from the first hospital. Although alert, he was disoriented in time, giving the date as that on which he had been admitted originally to hospital 4 days previously. There were no other cognitive abnormalities. He was treated with chlorpromazine and his symptoms receded over the next 3 days. At this time he revealed that he had been taking Actifed linctus, Benylin Forte and phenylephrine nasal drops for some weeks before admission. His Actifed consumption approached one bottle a day. He had taken small doses of Librium and glutethamide for many years to calm himself, but had had no glutethamide for more than a month before his admission. A urinary drug screen for cannabis, amphetamines, barbiturates and opiates was negative. He recovered completely from his psychosis, into which he retained full insight, and was discharged 5 days after admission. He has subsequently been treated with tricyclic antidepressant for anxiety and depressive symptoms and remains well at 2-year follow-up.

Discussion

The main constituent of Contac 400 is phenylpropanolamine (50 mg) which is structurally similar to amphetamine. Contac 400 also contains small quantities of belladonna alkaloids (0.25 mg). This is less than one-tenth of the maximum equivalent recommended dose of hyoscyamine. Actifed linctus contains pseudoephedrine, structurally similar to methylamphetamine, and an antihistamine triponidine hydrochloride. Benylin contains diphenhydramine hydrochloride and dextromethorphan. There have been several reports linking cold remedies with psychosis.

Sankey *et al* (1984) described visual hallucinations occurring in three children receiving Actifed preparation in the recommended doses.

Leighton (1982) reported a case of paranoid psychosis occurring in a 27-year-old man with stable bipolar affective illness following abuse of Actifed. The psychosis occurred in clear consciousness and in the absence of mood change and lasted 12 days, settling the day after his admission. His symptoms had cast doubt on his diagnosis, and the history of Actifed was not revealed until follow-up 10 days after discharge.

Norvenius *et al* (1979) cited five cases of psychosis, three in children, following phenylpropanolamine ingestion. Two of the children were confused and the third experienced visual hallucinations and a *grand mal* fit. A 25-year-old woman experienced sleep disturbance, "vivid paranoid misconceptions" and muscular twitchings in the legs. The symptoms disappeared 24 hours after the drug was stopped. A 17-year-old demonstrated a "mania-like psychosis" with aggressive behaviour on three occasions before the use of phenylpropanolamine was revealed.

Cornelius *et al* (1984) described "paranoia, homicidal behaviour and seizures" after phenylpropanolamine abuse in a woman with borderline personality and a history of polysubstance abuse. Chaplin (1984) has noted reports of the use of phenylpropanolamine as a "street drug" or "pseudo-speed". Diaz *et al* (1979) described the chronic abuse of pseudoephedrine in a chronically depressed patient with habituation to the drug but no psychotic symptoms.

The history initially taken from patients may not reveal the fact or the extent of drug usage, and routine screening for drugs may be negative. The clinical presentation may show striking psychotic symptoms without obvious clouding of consciousness. Confusional elements suggesting a toxic cause may be absent or brief. In the first case described here, these features were minimal and cleared soon after admission, the psychotic symptoms persisting for many weeks. In the second case, the confusional elements were more apparent, but the psychotic features persisted for 7 days.

It may be that patients with borderline personalities or affective disorders are particularly at risk.

Patients presenting with paranoid psychoses should be questioned about proprietary medications as well as prescribed and illicit drugs.

Encephalitis Lethargica, a Contemporary Cause of Catatonic Stupor
A Report of Two Cases

Two cases of catatonic stupor are described due to presumed encephalitis lethargica. Catatonic and obsessional phenomena in the setting of a depressive psychosis associated with a movement disorder may constitute a post-encephalitic syndrome.

Fifty years after the original description of encephalitis lethargica by Von Economo (1931), the cause remains enigmatic. Its natural history has the characteristics of an encephalitic disorder due to a neurotropic virus: recent epidemiological studies confirm Von Economo's original suspicion that it is related to influenza (Ravenholdt & Foege, 1982). The illness, however, was established as an entity by its neuropsychiatric sequelae, particularly Parkinsonism, oculogyric crises, movement disorders and a wide range of chronic psychiatric illnesses, especially psychopathic and psychotic states. Catatonic states occur in both the acute and post-encephalitic states of the illness and may develop quite independent of any psychotic symptoms (Davison & Bagley, 1969). The amyostatic–akinetic form of encephalitis lethargica was the third most common form of presentation of the illness in the 1918 epidemic, and as a result it came to be known as 'epidemic stupor'. Two recent cases of acute catatonic stupor are reported for which no adequate physical cause could be defined. That these cases were probably due to encephalitis lethargica is suggested by their resemblance to the post-encephalitic states of stupor described by Von Economo (1931).

Case reports

Case 1

A 23-year-old single male mechanic was admitted mute, akinetic, incontinent of urine and with severe blepharospasm. He adopted and maintained imposed postures for 10–15 minutes and would stand for hours in a bowed posture with flexed elbows and extended fingers. He had many compulsive rituals which involved sniffing and grunting and which occurred prior to eating food. He would communicate by answering 'yes' by moving his eyes horizontally or 'no' by a vertical movement. When he could be induced to stand and walk he performed a complex series of steps in the form of a square before entering doors.

His early development and parental relationships were normal, and in adolescence he had been a jovial and well adjusted youth. A depressive illness began three years previously and was thought by his parents to coincide with the suicide of a friend and the breakdown of a relationship with a girlfriend. He developed sleep inversion and according to his mother "turned night into day". His face became swollen in the region of the parotid glands and he lost weight. He was referred to Newcastle General Hospital where a full neurological investigation including CAT scan, LP and EEG were all normal. He lapsed into a catatonic stupor and was treated by abreaction, sodium pentothal interviews, and finally ECT, which produced some improvement.

The following year he again became depressed and would spend many hours in the bathroom counting and taking his clothes off in a precise sequence. This would involve sniffing and grunting and he would become angry if interrupted. He would 'freeze' during some movements such as eating or standing. He had two further hospital admissions but no firm diagnosis was ever arrived at. He was given further courses of ECT, behaviour therapy and lithium, and eventually improved.

He was then referred to Withington. All investigations were repeated and found to be normal. There were again no features of schizophrenia: he was severely dehydrated, weighed 84 lb and was hypotensive (BP 90/60). He was given intravenous fluid and ECT to a total of 14 treatments. He improved, and began to swallow spontaneously and move around his bed. At this point the possibility was considered that his catatonic stupor was due to encephalitis lethargica, and a trial of l-dopa with benserazide (125 mg t.d.s.) was given. Further improvement occurred and he began to speak spontaneously after 12 weeks of mutism. He remained, however, inert, lacking in spontaneity, and it was decided to give him flupenthixol 40 mg fortnightly intramuscularly. At this stage he was able to dress, walk and converse freely and over the next two weeks his rituals subsided completely. He was finally discharged home after three months. His mood was still morose, but he did interact with other patients, and he weighed 112 lbs. When seen at follow-up six months later his progress had been maintained and he was living a reasonably normal life at home.

Case 2

A 17-year-old male had a three-weeks history of an acute depressive illness in which he developed secondary delusions that he had contacted typhoid and was infecting his family. He took a small overdose of an antihistaminic (Piriton) and was admitted to hospital. On transfer to the psychiatric unit three days later he was mute and akinetic, and had marked negativism, hypertonia of his limbs and flexibilitas cerea. When he could be induced to move he would 'freeze' in fixed postures. He was incontinent of urine and had a low grade pyrexia. Physical examination was normal apart from hypotension (BP 90/70), attributed to dehydration. An EEG was the only abnormal investigation and showed diffuse, asynchronous delta and theta activity compatible with an encephalopathy. After rehydration with intravenous fluids and a course of ECT × 12 he improved and his catatonic phenomena disappeared. He remained amnesic for the period of his illness. His EEG prior to discharge had improved despite the course of ECT. He was seen again two years later when a report was requested for him while he was on remand in prison. Apart from poverty of expression and a lack of sponteneity, there were no other psychiatric or neurological symptoms.

Discussion

Catatonic phenomena which occur during the course of a depressive illness are uncommon, but they were a prominent feature in both these cases and remitted with ECT. Kraepelin included catatonic states within his concept of dementia praecox and considered they had a poor prognosis. This view was subsequently challenged and some forms of catatonic stupor were thought to have a good prognosis and to be more closely related to manic-depressive disorders than to dementia praecox (Hoch, 1921). Both these cases exhibited severe catatonic phenomena in the setting of depressive psychosis and resembled the cases described as 'Benign Stupor' by Hoch. He raised the possibility that his cases may have been due to encephalitis lethargica, which had just been described.

The triad of catatonic, obsessional and depressive phenomena, as in case 1, occurring in the absence of schizophrenic symptoms, is suggestive of encephalitis lethargica, while the movement disorder, particularly blepharospasm with a history of sleep inversion, reinforces this possibility. Lewis (1957), in his review of obsessional states, acknowledges the relationship between encephalitis lethargica and obsessive-compulsive behaviour.

Case 2, by contrast, presented as an acute depressive psychosis with catatonia and a recurrent pyrexia. No other schizophrenic phenomena were ever present and no alternative organic aetiology was ever advanced. This acute catatonic state resolved with ECT and closely resembled the amyostatic-akinetic syndrome that occurred in over a third of acute cases of encephalitis lethargica described by Von Economo during the 1918 epidemic.

A wealth of clinical evidence has accrued over the past 50 years to confirm Von Economo's original belief that encephalitis lethargica is a pathological and clinical entity; it still occurs in sporadic form today and is the antecedent of much chronic psychiatric illness (Hunter, 1973). It is now generally accepted that catatonic states are symptomatic of a neurological illness, and the possibility of encephalitis lethargica should be considered in the differential diagnosis of cases of catatonic stupor.

A Case of Affective Psychosis following Bereavement in a Mentally Handicapped Woman

Mentally handicapped people are increasingly being subjected to the stresses of everyday life, and bereavement represents a particularly potent stress. This report considers the case of a mentally handicapped woman whose difficulty in mourning and expressing and sharing grief had a profound effect on her recovery from bereavement and led to her developing an affective psychosis.

Bereavement represents a highly significant life event which may precipitate major depressive or other psychotic illness; our knowledge of bereavement in mentally handicapped people and how they cope with death, however, is limited (Oswin, 1981). Increasing numbers of mentally handicapped people are now living to middle age (Tait, 1983); they are often cared for in the community by ageing relatives or carers and consequently more handicapped people are experiencing bereavement than was formally the case. Parkes (1964) gives evidence to suggest that a correlation exists between bereavement and mental illness in people of normal intelligence, and it is likely that the same is true for mentally handicapped people.

Case report

A 47-year-old moderately mentally handicapped woman (IQ Stanford Binet 50) was admitted to the acute treatment ward of a mental handicap hospital after she had become increasingly unmanageable at her hostel and training centre.

There is no known cause for her mental handicap and there is no known past history of mental illness in her family. She has had no previous psychiatric illness, although she has been described as having an anxious personality; she has a long history of chewing her nails. The patient has good self-care skills, being able to feed, dress and toilet herself; she is unable to read or write but enjoys simple craft activities; she is capable of helping with simple domestic tasks.

The patient lived with her parents uneventfully until four years ago, when her mother suddenly died. She was described as having a very close relationship with her mother. Following her mother's death the patient was noted to have become disturbed and overactive. She was found wandering about in the local town at all hours of the day and night in search of her mother; because of this she earned herself the nickname "The Wanderer". Shortly after her mother's death she went to live in a local authority hostel, as her elderly father could no longer manage to look after her at home. Although she attended her mother's funeral, she did not talk about her mother's death. Her wandering behaviour continued for a few years but eventually stopped. She remained in regular contact with her father.

A year ago the patient's seventy-six-year-old father was diagnosed as suffering from carcinoma of the prostate gland; the patient was informed of this and appeared to understand that the condition would limit his life. Shortly after she was told this, the wandering started again. She became very restless and agitated and was difficult to manage in the hostel and the adult training centre. About this time she was referred to the psychiatric services and it was felt that she was undergoing a symbolic anticipatory mourning reaction. No clear evidence of clinical depression could be found at this time.

Several months later her father died; she attended his funeral but again she became extremely agitated, wandering away from the hostel and pestering the neighbours in the vicinity of her old home. She was sleeping very little, was overactive and had little interest in food; she also admitted to hearing her father talking to her during the night. She was started on thioridazine 25 mg t.d.s., 100 mg at night; her condition quickly improved.

After two months, however, she started to become increasingly withdrawn; she lost interest in food and her weight decreased by one stone. She had no spontaneous conversation and avoided contact with other hostel residents and staff. Her sleep was disturbed, she was weepy and very restless. Her self-care had deteriorated markedly and she began to smear faeces. She was diagnosed as suffering from severe depression; at the time of admission her score on the Hamilton 17-Item Rating Scale for depression was 29, which supported the diagnosis of severe depression. Antidepressant medication was gradually introduced to a final dose of trimipramine (150 mg at night), and over the next six weeks her condition began to improve. She started to attend occupational therapy, her sleep and appetite improved and she was now able to talk about the death of her parents, which was being encouraged. Her current score on the Hamilton Rating Scale is 8.

It became apparent from discussions with the nursing staff that her relationship with her father just before his death had become very disturbed. Previously they had had a close relationship, but following his illness the father became unable to cope with his daughter's constant pestering, and on several occasions he had beaten her off with his walking stick in his attempt to make her leave him alone. Her feelings towards him were clearly ambivalent and this may have made it more difficult for her to come to terms with his death.

Discussion

Reactions following bereavement have been well described (Lindemann, 1944). Feelings of shock, denial and alarm are common initially, followed by a mourning phase in which searching for the dead person may occur. Transient hallucinatory episodes are common in the normal bereavement process, as are symptoms of depression. After about 6–8 weeks, however, these symptoms usually fade, and in successful mourning, acceptance of the loss usually occurs after 6–18 months. Parkes (1964) describes a typical mourning in which there may be a serious prolonged impairment of function or a precipitation of serious psychotic illness.

Following the death of her mother, the patient displayed wandering or searching which could be seen as being part of a normal grieving process, but its prolongation was abnormal. At this time she not only suffered the death of her mother, but was also moved out of the familiar surroundings of the family home, she lost the daily contact with her father and also had to begin making relationships with a new group of people previously unknown to her. These changes, which occurred suddenly and for which she was completely unprepared, would have constituted an overwhelming degree of distress, which she was probably never able to come to terms with satisfactorily.

The mentally handicapped have a limited ability to conceptualise (Bihm & Elliott, 1982); this may have prevented the patient from coming to terms with grief after her mother's death, which was probably still unresolved at the time of her father's illness. The anticipated loss of her father several years later caused a recurrence of her initial symptoms, but with greater severity. After her father's death she became acutely agitated; she was treated with thirodazine, but she later went on to develop symptoms of a severe clinical depression.

The diagnosis of psychiatric illness in the mentally handicapped in notoriously difficult and some of the typical symptoms may not be displayed or expressed (Reid, 1972). Some writers have queried in the past the capacity for the mentally handicapped to become depressed (Herskovitz, 1941). It would be unreasonable to suppose that mentally handicapped people do not develop affective psychosis in the same way as people of normal intelligence, and stress may be an important precipitant.

Penrose (1972) indicates that the mentally handicapped react more severely to changes in the environment than do people of normal intelligence. Day (1985) believes that mentally handicapped people living in the community are living a more stressful life than people who are not mentally handicapped, and that death of a carer is a particularly potent stress.

Mentally handicapped people are often shielded from death and they may be prevented from attending funerals. Their lives may be profoundly altered following the death of a care-giver (Bicknell, 1983); this, coupled with their reduced intellectual capacity to come to terms with the loss, may result in a considerable degree of distress which may be unnoticed. It seems likely, therefore, that the mentally handicapped are going to be a group subject to significant morbidity following bereavement. It is hoped that research will be done to assess the full extent of the problem and to explore methods which can be employed to minimise distress (McLoughlin, 1986).

Short-Cycle Manic–Depressive Psychosis in a Mentally Handicapped Child without Family History

A Case Report

Diagnosis of classic psychiatric illness in mentally handicapped individuals remains difficult. Manic–depressive illness has previously been reported in both pre-pubertal and pubertal children with a mental handicap and with a family history. This paper reports a case of manic–depressive psychosis in childhood, with no family history, short-cycle mood swings and good response to lithium therapy.

John is now 15 years old. He was referred three years ago for psychiatric assessment, with a five-year history of mood swings and associated behavioural disturbances.

History

John is the elder of two boys. He was a full term normal delivery, to a healthy female in her mid-20s, and weighed 8 lb 14 oz. Early development appeared normal except for a persistent tendency to vomit small amounts. At the age of 18 months his development slowed down, speech ceased to progress and his parents sought the advice of a paediatrician. Between the ages of two and three his behaviour became clearly overactive; he suffered several minor head injuries at this age, but with no loss of consciousness or obvious repercussions. He has had no serious physical illnesses. John's early education was in a specialist unit for speech-retarded children. At the age of seven he underwent extensive psychological assessment which revealed that he was functioning cognitively at the 5 year level on the Merrill–Palmer Scale (Stutsman, 1931), but that language skills were at 3–3½ year stages on the Reynell Department Language Scale (Reynell, 1969). He was diagnosed as having a developmental language disorder.

At the age of nine he was accepted for education at a specialist school for autistic children, where he is a weekly boarder. While John does exhibit various autistic traits, including obsessional behaviour and reversal of pronouns, throughout his childhood he has been described as affectionate. The primary diagnosis is one of moderate mental retardation of unknown cause. He has made little academic progress in the last four years, but his self-care skills have improved. Further recent testing on the British Ability Scales has confirmed his intellectual limitations.

His mood swings are substantiated by school records: associated periods of pallor have been investigated by paediatricians, without any significant abnormal findings.

Prior to treatment, behaviour was monitored for 18 months, and a clear cyclical pattern to the mood swings emerged, substantiated by daily school and parental reports.

When well, John presents as a clean, sociable boy, responsive to and seeking affection. This phase is followed by a gradual period of withdrawal. John looks pale and ill, he is reluctant to eat or speak. He wakes early in the morning; he soils and wets himself. He sometimes cries for his "mummy", he headbangs and he has been heard to say "I can't stand it any more". He gradually returns to normal. This is followed by a phase when John becomes increasingly restless and distractible. His mood is incongruously jolly; he is overcome with waves of noisy hilarity. His speech becomes more rapid, its content fantastic and there is flight of ideas. His behaviour becomes "uncontrollable", with bouts of unexplainable aggression: he breaks things, throws his clothes out of the window and smears faeces. He gradually settles and returns to normal. Each phase lasts approximately 14 days.

In spite of extensive questioning, no family history of psychiatric illness has been elicited. A maternal great uncle had a developmental speech disorder, but was of normal intelligence.

Treatment

John was commenced on lithium therapy. Therapeutic blood levels were achieved. His behaviour continued to be monitored via daily reports from school and home: there was marked attenuation of mood swings, with an associated marked improvement in school progress.

After 12 months of treatment, the parents requested discontinuation of lithium therapy, believing much of his improvement to be attributable to "growing up". Within two weeks of cessation of lithium, John's behaviour deteriorated dramatically into a restless phase. Therapy was recommenced and he gradually settled.

Discussion

The reported case raises several interesting points. Manic-depressive illness in childhood is still a relative rarity, and its occurrence in a mentally handicapped child is even rarer and more likely to be missed (Hucker, 1975). Hucker's case had a strong family history, as well as evidence of precipitating events, neither of which are found in this case. Short-cycle manic-depressive illness has previously been reported in mentally handicapped adults (Reid & Naylor, 1976), but not children.

Diagnosis of manic-depressive psychosis in the mentally handicapped is fraught with difficulty, behaviour due to illness often being attributed to the handicap, or even misdiagnosed.

Rivinus & Harmatz (1979) have commented on the eminent treatability of manic-depressive psychoses. They reported a 100% success rate treating mentally handicapped adults with the disorder with lithium. Treatment of all childhood psychiatric disorders tends to be more conservative than in adulthood.

ECT has been used in childhood bipolar illness, and Hassanyeh & Davison (1980) report on the use of ECT and the use of lithium in ten manic-depressive, intellectually normal children.

Accurate diagnosis and effective treatment are never more vital than in childhood. The mentally handicapped already have their intellectual impairment as handicap; therefore identification and treatment of psychiatric illness are essential to enable them to achieve their maximum potential.

Acknowledgements

I would like to thank Mrs Kingdom and the staff of Hope Lodge School for their co-operation and help in monitoring, assessing and treating this patient.

Neurosyphilis – a Treatable Psychosis

A patient presenting with mixed affective symptoms was found to have active neurosyphilis after intermittent cognitive impairment suggested an organic cause. Most of these symptoms resolved after treatment with penicillin.

Neurosyphilis has long been associated with psychiatric syndromes, but it now rarely presents to the psychiatrist at an acute, treatable stage. With the introduction of penicillin the number of cases has diminished and in many psychiatric centres serological tests for syphilis are not performed routinely. The widespread use of antimicrobials may have also led to the masking of the early stages of the disease because of coincidental therapy for other conditions. We report here a case of neurosyphilis presenting as an organic psychosis, which resolved with penicillin.

Case report

A 43-year-old, unemployed, single, homosexual man was admitted to a psychiatric hospital (Mapperley Hospital) informally from police custody following several incidents of bizarre and destructive behaviour during the preceding fortnight. Mental state examination revealed a mixed affective state with intermittent clouding of consciousness and loss of memory. Initial biochemical and haematological profiles were normal, but because of his intermittent cognitive impairment, additional laboratory investigations were performed. Syphilis serology showed the following titres: VDRL 64, TPHA 128 and FTA (Abs) positive. He was Hepatitis B surface antigen negative, and HIV III antibody negative, and chest X-ray was normal. Lumbar puncture was carried out and this yielded results characteristic of active neurosyphilis, the cerebrospinal fluid (CSF) being Igm FTA positive and having a lymphocyte count of 14/μl. Psychological assessment demonstrated an acquired cognitive deficit and NMR scanning revealed no structural abnormality.

He was treated with penicillin and his mental state improved rapidly; he was discharged from hospital on no drug therapy. Five months later he became paranoid and suspicious, necessitating admission to a day hospital. No cells were seen on repeat examination of the CSF so he did not receive a second course of penicillin.

One year after his relapse he had remained free of paranoid symptoms with a mild degree of cognitive impairment.

Discussion

Recent surveys (Nordenbo & Soresen, 1981; Alani & Millac, 1982) suggest the incidence of neurosyphilis to be two per million population per year. Of these, approximately 25% present with a psychiatric disorder. The remainder present with cerebrovascular accidents, visual problems, learning deficits and on incidental testing.

Abnormalities of the CSF may occur at any stage of the disease and specific serological tests on CSF are positive in every untreated active case. They may or may not revert following treatment. Residual neurological damage following treated neurosyphilis is a frequent finding. Although there is evidence that unnecessary laboratory investigations are often carried out in psychiatric patients (Ferguson & Dudleston, 1987), in those patients whose mental state suggests an organic component, serological screening tests for syphilis are still essential. This case serves as a good illustration.

Acknowledgements

We should like to thank Professor B. S. Worthington for his help in carrying out the NMR scan, Dr J. B. Bittiner for advice on treatment, and Dr T. Riordan for carrying out the immunological tests.

A Search for Sub-Clinical Arteriosclerotic Dementia

SIR: McDonald & Sudhaker (*Journal*, July 1987, **151**, 134–135) state that "the high discordance between the pathological findings and the ante-mortem diagnosis of arteriosclerotic dementia is well known". Such discordance was not evident in my own cases from an American mental hospital (Birkett, 1972) in the days before CT scans. The autopsy findings were predicted with considerable accuracy.

Proving or disproving the existence of arteriosclerotic dementia without infarcts is difficult. The closest we have so far come is probably in Corsellis's (1962) study. He found cerebral arteriosclerosis without infarcts to be significantly commoner in demented patients than in matched controls from the same hospital with functional psychosis.

Until such studies can be replicated it is probably best to follow Alzheimer (1894) and call the condition mental disorder based on arteriosclerosis ("Seelenstoerungen auf arteriosclerotischer Grundlage"), specifying the presence of dementia and the presence of proven infarcts.

Review of *Behavioural Psychotherapy*

SIR: Mackay (*Journal*, July 1987, **151**, 136) implies that the behavioural interventions described in this book are applicable only to "simple phobias and obsessional disorders". He seems to have missed most of the book's content. Of its eleven detailed case histories with clinical management protocols, only two concern simple problems. The remaining nine case illustrations are of complex disabling difficulties, including severely handicapping agoraphobia, social skills deficits, sexual dysfunction, sexual deviation, eating disorder, irritable bowel syndrome, and stammering. Many of the patients whose behavioural treatments are detailed are among the most complex and difficult to be found in psychiatric practice. Mackay's suggestion that adding a cognitive approach enhances behavioural treatment flies in the face of most controlled evidence in the field of anxiety disorders (reviewed by Marks (1987), chapter 14).

Range of Mental Illness Among the Elderly in the Community

SIR: I am perplexed as to why Copeland *et al* (*Journal*, June 1987, **150**, 815–823) consider their elderly mental ill as divided into Caucasian, Mongoloid and Negroid "races". These are now abandoned terms in biological anthropology, and have no obvious relevance, either, to current (socio-political) use of the term 'race'. What did the interviewers mean by describing an individual as 'Negroid'? Most

Afro-Caribbeans have, for instance, White ancestry. Using the Victorian definitions of 'Caucasian' (predicated upon 'Indo-European' linguistic patterns), South Asian immigrants and their children born in Britain are 'Caucasian'. Or do the authors mean 'White' by 'Caucasian'?

The ambiguous and tendentious use of an idiom which connotes a simple causal relationship between phenotype, genotype, behaviour, and social experience is disturbing. What is wrong with the terms (a) *ethnic group* (as currently perceived), (b) *race* as a sociological term, or (c) quantitative measures of population genetics, as variously needed?

Estimates of various ethnic groups in the general population *can* be derived from the 1981 Census head of household figures using the Labour Force Survey correction factors.

ROLAND LITTLEWOOD

Department of Anthropology
University College London
Gower Street
London WC1E 6BT

SIR: We thank Littlewood for giving us an update on the latest anthropological view for describing the demography of samples. To clarify the use of terms in our study, 'Negroid' refers to those individuals who have the appearance of some African ancestry, and 'Caucasian' refers to Indo-Europeans, white and non-white.

Clearly, associations in themselves cannot be used to imply a causal relationship, simple or otherwise.

Mania Following Head Injury

SIR: Clark & Davison (*Journal,* June 1987, **150,** 841–844) argue that the infarct their second patient was noted to have in the left frontal region during a manic episode was unlikely to be causative because Cummings & Mendez, in their review on the association between mania and the site and nature of intercerebral lesions, did not find any reports of mania associated with cerebrovascular lesions in the left frontal region. There are at least two case reports of mania associated with lesions in the left frontotemporal region: Jampala & Abrams (1983) reported a 52-year-old man with recurrent manic episodes with onset at the age of 24 following a rupture of a left middle cerebral artery aneurysm. Herlihy & Herlihy (1979) have described a 58-year-old lady with manic episodes following a haemorrhage in the left middle cerebral artery. Both these patients were noted to have lesions in the left frontal and frontotemporal region.

Clark & Davison also note that the two previously-reported cases of mania associated with head injury occurred in younger patients and that this is contrary to the commonly held view that secondary mania is more common in the elderly, as suggested by Krauthammer & Klermann (1978). Shukla *et al* (1987) studied 20 patients who developed mania following closed head injury, and the age at first psychiatric episode in their patients ranged from 17 to 42 (mean = 27.5 years). Brackens (1987) reported a lady who developed mania at the age of 48 following head trauma. So, from the above reports, it appears that mania can occur at any age following head injury.

Carbamazepine is very effective in the treatment of secondary mania (as suggested by Jampala & Abrams (1983)) and this should be considered as one of the first line agents in addition to lithium.

Schizophreniform Episode Following Measles Infection

SIR: The description by Stoler *et al* (*Journal,* June 1987, **150,** 861–862) may be the first adult case reported in the literature, but Nunn *et al* (1986) have previously reported four cases where there was an association between a viral illness (measles, rubella, varicella, and herpes) and adult-type psychosis in children. All the children had some neurodevelopmental disorder rendering the children more vulnerable to psychosis once infected by a virus.

Nunn *et al* drew attention to the need to clarify the role of the virus in the aetiology and suggested a hierarchy of questions exploring the strength of relationship between viral presence and psychosis: (a) does the patient have a systemic viral illness? (b) is the virus present in the cerebrospinal fluid (CSF) or is there evidence of an immunological response even if the virus is not present? (c) is the virus actually infecting the central nervous system (CNS)? and (d) is the viral infection of the CNS responsible for the observed psychosis?

Stoler *et al* would not appear to have sufficient evidence to answer the second question as, in the case they describe, the presence of monocytes in the CSF only indicates involvement on the meninges and is not adequate proof of brain tissue involvement. This highlights the need for rigorous use of more sophisticated techniques to demonstrate CNS involvement by viral agents (e.g. virus isolation, CSF banding) before moving from temporal associations to causal relationships.

Electrodermal Response as a Monitor in ECT

SIR: Simpson & Hyde (*Journal*, April 1987, **150**, 549–551) give a description of the "cuff" technique (Adderley & Hamilton, 1953) for monitoring ECT.

I regret to have to point out that the description is incorrect. Before giving ECT, a sphygmomanometer cuff is applied to one arm and the pressure raised to above that of the systolic blood pressure. The suxamethonium is then injected through another vein, and after all the muscular twitching has stopped the sphygmomanometic cuff is released and the electric shock administered.

One should be wary of forcing a muscle to contract vigorously when its blood supply has been cut off.

MAX HAMILTON

School of Medicine
University of Leeds
30 Clarendon Road
Leeds LS2 9NZ

SIR: We thank Hamilton for clarifying details of his technique. It does not invalidate the result of our brief study, as the convulsion was observable as by the original method. Total systolic occlusion time was very brief and no harmful sequelae have been observed.

Neuroleptic Malignant Syndrome or Lithium Neurotoxicity?

SIR: Jee (*Journal*, April 1987, **150**, 568–569) argues that Abbott & Loizou (*Journal*, January 1986, **148**, 47–51) in their review of the neuroleptic malignant syndrome (NMS) appropriately excluded the data from Cohen & Cohen (1974) as an example of this syndrome on the basis that their evidence was inconclusive.

However, Abbott & Loizou had cited the observations of Baastrup *et al* (1976), whose study "was carried out in order to determine whether the syndrome described by Cohen & Cohen is, in fact, seen frequently in patients given both lithium and haloperidol", without reference to Cohen & Cohen's original findings. We were concerned by this omission and our own correspondence (*Journal*, September 1986, **149**, 385) simply drew attention to the descriptive superficial resemblance of the Cohen & Cohen cases to NMS.

We think that the evidence for lithium neurotoxicity in these cases as proposed by Jee is no stronger than our own postulations. He quotes Schou (1984) who reviewed case reports on 40 patients with persistent neurological sequelae after lithium intoxication, but fails to mention Schou's special comments on the Cohen & Cohen cases whom he regarded as atypical. Schou noted that none of them had particularly high serum lithium concentrations compared with the group as a whole; also, there was a high fever of unknown origin in all four cases, whereas in the rest of the group fever, where it was documented, was identified with a somatic illness in all but one case. Finally, on follow-up 2–10 months later none of these patients had the clear-cut cerebellar syndrome characteristically attributed to lithium toxicity.

More recently, Goldney & Spence (1986) in a retrospective study of 60 manic patients treated with neuroleptic drugs alone and 69 manic patients treated with neuroleptic drugs and lithium could demonstrate no significant differences in side-effects between the two groups, including comparisons made between patients on haloperidol only and those treated with haloperidol and lithium. Their comments thus add further weight to the original observations of Baastrup *et al.*

Doubts regarding the true cause of the clinical events in Cohen & Cohen's patients will never be completely resolved, although the validity of their own postulate of a lithium/haloperidol interaction seems to be diminishing as the full explanation.

Tuberous Sclerosis and the Autistic Syndrome

Sir: Lawlor & Maurer (*Journal*, March 1987, **150**, 396–397) described tuberous sclerosis presenting with autistic behaviour. Reported cases of this association are rare; however, I believe that it is not that uncommon. I can recall seeing three such cases. The following is an example.

Case Report: A male was born following a delayed labour and assisted delivery but recovered normally. Within 5 days he was found to be a restless baby with much screaming and difficulty in feeding. He walked at 12 months, but at 15 months he started to have temper tantrums. Subsequently, it became apparent that he had delayed speech. Later he developed overactive and disruptive behaviour, which eventually lead to his admission to a child psychiatry unit at the age of 3 years. He was diagnosed as having a profound language disorder with severe autistic traits, but was of potentially normal intelligence. Physical examination at this time showed no neurological abnormalities, but roughened skin on the cheeks and between the shoulder blades was noticed. Over the next few years there were many reports of poor social interaction, delayed speech with reversal of pronouns, mannerisms, inappropriate emotional reactions, resistance to change, and unusually good reading ability. At the age of 6 he developed epilepsy, which remained well controlled with anticonvulsants. At various times during his childhood he attended an ESN (M) day school, several private residential schools, and a school for autistic children.

At the age of 9 he was referred to me by the social worker because of difficult and aggressive behaviour. Physical examination revealed clear facial adenoma sebaceum, several areas of depigmented skin on the trunk and legs, and the previously recorded roughened areas between the shoulder blades. The family was advised of the possible diagnosis of tuberous sclerosis. Both parents were very intelligent and they had a normal daughter. The only significant feature in the family history was that the mother had had a mentally handicapped half brother who died at the age of 22 years with a tumour of the liver. Further physical examination of the family by a consultant geneticist revealed that the mother had a slight skin lesion in keeping with the diagnosis. The father and the sister appeared to be unaffected. The parents were advised of the significance of the findings, but had already decided to have no more children.

The patient has continued to present problems of management, especially aggressive behaviour, and still has many autistic features. He attends an Adult Training Centre and lives in a Social Services hostel.

The above illustrates not only the association of the two conditions but also supports the authors' conclusion that a suspicion of tuberous sclerosis should be aroused if autistic features and epilepsy coexist. It also suggests that history taking and physical examination in child psychiatry should always involve a genuine appreciation of genetic factors.

Delusional Parasitosis

Sir: Macaskill (*Journal*, February 1987, **150**, 261–263) reports the first case of a non-pharmacologically induced remission of delusional parasitosis. Hunt & Blacker (*Journal*, May 1987, **150**, 713–714) suggest that this was a mild form of the disorder, associated with clear precipitants. I report two further cases of spontaneous remission.

Case reports: (i) A 51-year-old housewife with no previous history of medical or psychiatric illness presented to a dermatology clinic with a one-month history of parasites in her hair. She described hearing them moving, and could feel them burying into her scalp. She produced a matchbox containing skin scrapings as proof. There were no obvious precipitants, although she was under chronic strain through coping with her demented mother. The dermatologist found no abnormality, and prescribed no treatment. However, he concurred with her suggestion of a brief holiday in Spain. On her return two weeks later she was seen by the psychiatrist. She said the parasites had now gone, but was certain they had been present. There was no evidence of psychiatric disorder (CIS score = 7; HAD score = 4). She remained well one month later.

(ii) A 58-year-old shop assistant attended the dermatology clinic with a three-month history of delusional parasitosis. She claimed she had been infected by her sexual partner, and that she could now feel insects crawling under her skin, stinging her, and living in her anus. She also felt worms moving in her stomach. She felt dirty, and thought her body odour was offensive. She had attended her GP, a private dermatologist, and several alternative practitioners, but without benefit. She had had a genuine hook worm infestation as a teenager. She had also received antidepressants from her GP when she was 32 and 42, during times of marital stress.

When seen by the psychiatrist she had been ill for four months. Her beliefs were delusional in nature, and she recorded maximal conviction on visual analogue scales of intensity of belief. Other than fatigue there was little to suggest depression (CIS score = 21). She refused treatment. One month later she reported that she had passed a "worm" in her stools, and described a three inch long creature with horns. Since then the rest of the parasites had died, and she no longer felt infested. She still felt she had a dirty tongue and skin, and still felt self-conscious of her body odour (CIS score = 12).

Previous reports in the psychiatric literature have emphasised the intractable nature of untreated delusional parasitosis (Monro, 1980; Sheppard *et al*, 1986), unless as part of a depressive illness. In a questionnaire survey of dermatologists, Lyell (1983) identified 282 cases, and confirmed the generally poor prognosis, but claimed 13 had remitted. He also described one case history of a spontaneous remission after three months. Batchelor & Reilly (1986) used a similar method to obtain details of 55 patients. Although again confirming the poor prognosis, "a third had a duration less than a year" while one had "improved slowly on dermatological treatment only". The gloomy natural history reported by psychiatrists may partly reflect patterns of referral.

Lucid Intervals in Catatonia: A Neuropsychiatric Snare for the Unwary

SIR:

Case report: A 42-year-old woman with a recent history of treatment of a major depressive disorder with dothiepin (150 mg/day) suddenly became agitated, complaining of being unable to walk and that her mind was going blank. She was admitted in a state of retarded depression, but despite an increase in dothiepin (225 mg/day) continued to deteriorate. Her mental state fluctuated between mute immobility and terror-stricken agitation, for which she was given chlorpromazine (100 mg i.m.) on three occasions over a one-week period. She resisted all nursing care and had to be fed and toileted, at times exhibiting verbigeration, bizarre and stereotypical behaviour, and catalepsy. Diazepam (20 mg i.m.) prior to CT scanning produced a dramatic improvement, lasting several hours. She spoke coherently and started eating, before relapsing. Investigations, including CT scan and EEG, were normal. Full recovery followed after three bilateral ECTs, and she remained well at six-month follow-up.

Amylobarbitone sodium interview continues to be advocated as a diagnostic aid in distinguishing catatonia secondary to idiopathic psychiatric ('functional') disorders from those that are toxic-metabolic or neurological ('organic') in origin (Altshuler *et al*, 1986). Our patient's response would be a case in point were it not for the fact that the catatonic signs became apparent only after the introduction of neuroleptic treatment. Ainsworth (*Journal*, January 1987, **150**, 110–112) and Chick *et al* (*Journal*, July 1987, **151**, 130–131) describe similar results with benzodiazepine and barbiturate infusions in catatonia, due to viral encephalitis and structural brain damage respectively. Further doubt is thrown on the diagnostic value of these techniques by reports of temporary or permanent relief obtained in a case associated with pituitary adenoma (Sheline & Miller, 1986), neuroleptic-induced catatonia (Fricchione *et al*, 1983) and the neuroleptic malignant syndrome (NMS) (Lew & Tollefson, 1983), which clinically resembles an iatrogenic variety of Stauder's "lethal catatonia". In addition, Lim *et al* (1986) have reported dramatic responses to i.v. phenytoin in catatonia as a manifestation of non-convulsive status epilepticus.

Several lines of evidence suggest that catatonia is the product of disturbed central neuroregulatory-vegetative functioning. The similarity in symptomatology between the neuroleptic-induced and other varieties of catatonia may reflect a common pathophysiology, involving dopamine and GABA neurons in the mesostriatal and mesolimbic systems and hypothalamus (Fricchione, 1985). Dopamine agonists, e.g. dantrolene and bromocriptine, appear to relieve NMS by direct alteration of dopaminergic transmission, while barbiturates, hydantoins, and benzodiazepines, which interact with receptors closely related to the GABA/chloride-ionophore complex, do so indirectly, mediated by GABA feedback loops in the mesostriatal and mesolimbic systems. The relatively weak GABA-ergic properties of barbiturates may also account for the shorter duration of lucid intervals following amylobarbitone sodium infusion compared with those produced by benzodiazepines.

In view of the wide variety of conditions associated with catatonic states it seems doubtful whether a response to barbiturate or benzodiazepine infusion has any *diagnostic* validity, although the latter may be of therapeutic benefit, depending on the extent and localisation of underlying cerebral pathology. A safeguard against the pitfalls of the traditional 'functional/organic' dichotomy would therefore be to conceptualise catatonia as a non-specific neuropsychiatric syndrome, a final common pathway of response to an overwhelming psychiatric, neurological, or medical insult.

Sub-Cortical Dementia and the EEG

SIR: The review of the concept of sub-cortical dementia by Cummings (*Journal*, December 1987, **149**, 682–697) was timely, comprehensive and persuasive. A further body of evidence that can be cited in favour of the nosological distinction between cortical and sub-cortical dementia comes from the electro-encephalogram (Fenton, 1974). The EEG in the cortical dementias of the Alzheimer-senile type is invariably abnormal, characterised by diffuse asynchronous delta and theta dominant records. By contrast, the EEG of the sub-cortical dementias of Huntington's chorea, Parkinson's disease, post-traumatic encephalopathy, and post-encephalitic states is either normal or 'flat' low voltage in type. The vascular encephalopathies occupy a variable and often intermediate position between the two.

These differing EEG patterns in the cortical and the sub-cortical dementias must reflect the progressive disintegration of different neural systems, and is further evidence in support of employing this nosological classification of the dementias. We are at present attempting to carry out a double-blind assessment of the EEG in these two categories of dementia.

'Barking Mad'

SIR: "She had something that girl. She's mad, that's the worst of it. Bonkers, barking, round the bend". 'Barking mad' is a term in colloquial use which has started to appear in English literature as the line above, from John Welcome's 1968 play *Hell Is Where You Find It*, illustrates. In David Hare's play, *Plenty*, Sir Leonard Darwin observes that "in the diplomatic service it isn't as if a mad wife is any kind of professional disadvantage... Some of our senior men, their wives are absolutely barking". Despite such current use, barking is not described in psychiatric texts as a sign of mental illness. I have recently seen a patient in whom barking was part of the clinical picture.

Case Report: A sixty-year-old Irish divorcee had lived alone in a council flat since separation from her husband four years previously. Two months prior to the onset of symptoms she had retired from her work as a caterer. At presentation she gave a four-month history of feeling depressed and anxious with loss of appetite and energy. Two months previously, while on a shopping trip with her sister, she had started to grimace and make growling noises in a supermarket. She continued to make barking and growling noises, frequently on buses and in shops, until, finally, she was admitted for assessment.

While on the ward it became evident that her barking was partly under voluntary control: she was able to reduce its frequency, but not abolish it altogether, upon being asked to do so. She was agitated, but showed no clear evidence that she was suffering from a depressive illness. She was treated with diazepam (2 mg t.i.d.), and over the course of a month her agitation progressively resolved. She stopped grimacing and making growling or barking sounds and was discharged.

I wonder if others have observed this symptom which, even in the diplomatic service, would seem likely to confer some disadvantage.

Ofloxacin-induced Psychosis

SIR: The new quinolone derivatives, also known as gyrase inhibitors and widely used as potent chemotherapeutic agents, have frequently been implicated in causing central nervous system side-effects (Blomer *et al*, 1986; Cohen *et al*, 1984; Gleckman *et al*, 1979). Until now, only a few patients who have developed central nervous system side-effects have been seen by psychiatrists. We present two such cases, both induced by the latest gyrase inhibitor, ofloxacin (presently under clinical evaluation in the UK and US).

Case Reports: (i) A 28-year-old woman was given ofloxacin (200 mg po b.i.d.) over a course of 5 days for recurrent scalp infections. On the night of day one, she experienced a decreased need for sleep, and on the following day progressed to a hypomanic state with an overly cheerful mood, increased social and physical activity, restlessness, racing thoughts, and loss of appetite. Her condition did not change until day 4, when she appeared to enter a kind of intermediate stage with predominant depressive features, lasting until day 10 (ofloxacin was discontinued on day 5): she was dysphoric and irritable , with labile affect, complained of fatigue, loss of energy, indecisiveness, and lack of concentration. At the same time, she still experienced racing of thoughts, insomnia, loss of appetite, and a 10% loss of weight. During this time she also had four panic attacks. From day 10 to day 18 she progressed to a marked depressive syndrome with loss of energy, depressive mood, loss of interest in all usual activities, continued lack of appetite, and insomnia. After day 18, she improved rapidly; 25 days after the onset of symptoms she was back to normal. Our patient had no relevant psychiatric or family history and had not received any medication in the four weeks preceding her illness. Medical examination, EEG, CT-scan, and laboratory studies were normal, except for an elevated TSH (21.1 U/ml).

(ii) A 64-year-old woman had been treated with ofloxacin (200 mg po b.i.d.) for a complicated urinary tract infection. The drug was discontinued on day three, when she progressed acutely to a catatonic state with rapidly alternating episodes of stupor and excitement: short periods of mutism, catatonic posturing, and waxy flexibility changed within minutes to states of excitement with perplexity, screaming, verbigeration, and stereotypies. Her thinking became incoherent, with marked loosening of associations. At times she was perplexed, and partly disoriented in time and situation. She had religious delusions, auditory hallucinations, and recurrent optical illusions; all symptoms were present on days one and two after ofloxacin was discontinued. She was given chlormethiazol on days three and four, and improved within hours: she was oriented, and her thinking was coherent. She still complained of pressure of thoughts and distractibility. During the following 10 days she improved steadily and was almost back to normal on day 14, with partial amnesia for the duration of the psychosis.

This patient had had a psychiatric history with a poorly defined depressive episode in full remission, 15 years previously. Prior to admission, she had been given several spasmolytic and analgesic medications for urolithiasis, and had a history of compensated hyperthyroidism (TSH 0.98 U/ml, T3 75 g%, T4 8.37 g%). Medical examinations and other laboratory investigations were normal, and CT scan and EEG were negative.

The essential feature of case (i) was a bipolar mood disturbance, and our diagnosis according to DSM–III was organic affective syndrome. Using these criteria in case (ii), we diagnosed both an atypical organic brain syndrome and an organic delusional syndrome. According to ICD-9, our diagnosis in both cases was subacute organic psychosis.

Ofloxacin seems to be potent enough to produce different yet well-defined psychiatric syndromes. We have received an increasing number of reports on ofloxacin-induced psychoses. Further research should focus on ofloxacin's ability to generate model psychoses.

Oxymethalone and Aggression

Sir: An 18 year-old male, treated with oxymethalone for idiopathic aplastic anaemia, developed a temporary increase in aggression. I believe this to be the first report of such an association with anabolic steroids prescribed for therapeutic reasons and there have been no reports to the Committee on Safety of Medicines of similar cases. However, hypomania (Freinhar & Alvarez, 1985) and depression (Sheffer *et al*, 1979) have been described as a result of this class of drug. The use of anabolic steroids in sport has led to reports of increased aggression (Strauss *et al*, 1984). Doses, however, were idiosyncratic, excessive, not medically indicated, and often involved illicit drugs which purported to contain mixtures of somatotropin, a substance called "rhesus growth factor", and various anabolic steroids. They were usually taken in large quantities, far exceeding manufacturers' recommended therapeutic ranges. Overall, 35–80% of users reported an increase in aggression; of these, 75% found this to be a desirable effect.

Case Report: Within three weeks of commencing treatment with oxymethalone (150 mg daily), the patient had broken the nose of an acquaintance, smashed two expensive guitars and considerably strained the patience of his girlfriend. He was an intelligent, insightful young man, weighing 70 kg, who was studying for his 'A' levels, and who had every chance of gaining a place at university. He stated that his temper just 'snapped' following little or no provocation. Previously he had been a placid individual, and reports from his college tutor bore this out.

He was referred to psychiatric services after he had visited his GP, as he was worried either that his parents would eject him from the family home, or that he would end up in serious legal trouble, as a consequence of his actions. He was a modest drinker of alcohol (one pint of beer per week), and denied any other drug usage. His hobbies were unremarkable, and included listening to "heavy metal" music, of a variety which explored a rich seam of mysticism. He espoused philosophical ideals of peace and harmony. Exploration of his attitudes to his physical condition (which was responding well to treatment) revealed no major difficulties. There was similarly no evidence to suggest prior familial or other areas of interpersonal conflict. Previous medical history was unremarkable; there was no history of head injury. There was no family history of aggression or epilepsy. Mental state examination revealed no major abnormality other than the presenting complaint as described. Overall, he was an extremely pleasant young man.

The patient's haematologist confirmed that increased aggression had been reported within weeks of commencement of treatment. It was also felt that it was essential to continue the therapy for the next few months, depending on the haematological response.

In view of this, a cognitive/behavioural treatment plan was commenced. Within a fortnight, aggressive thoughts had diminished considerably, with only three being recorded, and no violent action had been taken on any of them. Pre-treatment levels were considerably higher than this, with daily aggressive thoughts, and perhaps weekly aggressive, remorse-inducing deeds having been reported. One month after starting this management the dose of oxymethalone was reduced by one-third.

This case indicates that in therapeutic doses anabolic steroids may induce aggression. It also shows that cognitive/behavioural techniques can serve to modify such anger and aggression. Finally, given the widely-reported illicit, uncontrolled usage of such substances by athletes and body-builders, the forensic implications of these observations may be considerable.

I am grateful to Dr Alan King for permission to report this case.

Book Reviews

Editor: Sydney Crown

Ethnic Psychiatry. Edited by CHARLES B. WILKINSON. New York: Plenum. 1986. 199 pp. $25.00.

This is an impressive book arising out of several years of collaboration between psychiatrists in North America; yet its relevance for the UK is particularly poignant. It is well written, and the layout allows a ready scanning of its ideas. The book provides working definitions of race, ethnicity, and minorities, and their relevance to mental health. It is concerned with American Indians, Black Americans, Spanish-speaking peoples, orientals, and Pacific islanders within North America. It is about minorities as defined as a group of people who are differentiated from others in the same society by ethnicity, race, nationality, or religion, and who occupy subordinate positions in the communities in which they reside. The minority group may be numerically smaller, but could constitute a majority as far as populations and size is concerned, e.g. the black population in some Southern states of the US. The exclusion of minorities is preserved by the retention of power of the dominant group; power that is used for economic, political, and sexual exploitation.

The impressive aspect of this book is the way it combines straightforward accounts of the history of the minority groups in the US, their present day psychiatric and mental health needs, and the political framework within which they exist. There is a link between the impact of racial discrimination and adverse mental health. Discrimination and racism are not avoided as major issues, and the United States has not become a melting pot; the authors state that this is unlikely to occur, and mental health professionals, as well as the majority and minority cultures, need to consider the rich diversity of minorities in pluralistic society.

There is a chapter on mental health of Black Americans which is a reminder of the history of discrimination in the US, with the effect it had on psychiatric treatment and more especially on psychotherapy. Hispanic psychiatric issues are the topic of chapter 3; there are over 14 million Spanish-speaking or Hispanic Americans in the US, and over 3 million Puerto Ricans. The tight family relationships in which members rely on each other for support and assistance are discussed, and their effects, both good and bad, on mental health described. The preservation of their language and the links between Latin America and North America are preserving these ethnic characteristics. The need for therapists to understand the explanatory models of the Hispanic group, and to take into account traditional beliefs and the extent of stigma associated with mental illness by Asian Americans and Pacific Island communities, is emphasised by Yamamoto.

The final chapter is an interesting review of American Indian mental health and the lack of a culturally relevant therapeutic approach. There were 300 distinct tribal groups in North America. Alcoholism, violence, suicide, and accidental death have increased in Indian people in the past 25 years. The reasons for this include cultural ambivalence, loss of traditional culture language and beliefs, loss of control over one's life, and a learned pattern of survival behaviour.

To this reviewer it is readily apparent that some of these minority groups, together with several others, exist in an equally cohesive form in the UK. The important contribution of this book to thinking in cultural and ethnic psychiatry is that it raises the question of why similar texts have not been produced in the UK. Maybe psychiatrists with practical clinical experience and a political sensitivity should begin to pool their creative resources more efficiently.

JOHN L. COX, *Professor of Psychiatry, Department of Postgraduate Medicine, University of Keele*

The Quality of Life of Cancer Patients (Monograph Series of European Organisation for Research and Treatment of Cancer (EORTC), Vol. 17). Edited by NEIL K. AARONSON and JORN BECKMANN. New York: Raven Press. 1987. 304 pp. $68.50.

To be able to recommend a book unreservedly is a rare pleasure. This monograph is a result of the work of the EORTC study group on quality of life. Recent years have seen notable advances in the treatment of cancer as judged by such criteria as reduction in tumour volume and increased duration of survival. Unfortunately, these improvements have not always been mirrored by improvement in patients' sense of well-being. This is largely due to the distressing side-effects of treatment, particularly certain chemotherapy regimens. Growing dissatisfaction among patients with what they perceive as dehumanised high-technology medicine has focused the attention of clinicians on the quality of life of cancer patients under their care. In basing their choice of treatment on a careful consideration of the balance between the beneficial and harmful effects of various treatments, clinicians need accurate data not only about duration of treatment but also about the quality of life of the survivors.

What is "quality of life" and how can it be measured? These are the salient questions addressed in the monograph. Topics considered here range from philosophical concepts of quality of life to practical problems encountered in psychosocial cancer research. There are sections on quality of life measurements in children with cancer, in adult patients, and in those who are terminally ill. Other chapters deal with such disparate topics as the weird but by no means wonderful quack remedies currently on offer to cancer patients, differences between physicians and their patients in perception of disease and treatment, and a study of self-help groups. The contributions are lucid, concise, and informative. It would have been helpful if abstracts had been provided at the beginning of each chapter and if the various authors had used the same reference system, but these are minor quibbles. This handsomely produced monograph makes a useful and interesting contribution to the young, rapidly developing discipline of psychosocial oncology, a discipline of increasing importance for psychiatrists in general hospitals.

STEVEN GREER, *Director, Cancer Research Campaign Psychological Medicine Research Group, The Royal Marsden Hospital, Surrey*

Mental Health and Primary Care: Dutch and Israeli Experiences. Edited by G. J. VISSER, J. M. BENSING and B. P. R. GERSONS. Utrecht, The Netherlands: NIVEL. 1986. 217 pp. fl 31,50.

This book consists of the papers and subsequent discussions from a symposium sponsored by the Dutch Israeli Cultural Treaty on the interaction between mental health services and the primary care sector. The aims of the symposium were for the participants from both countries and both disciplines to meet, share their experiences, and plan for future co-operation and collaboration.

The book, like the symposium, is divided into four sections. The first presents an over-view of the organisation of primary care and mental health services in Israel and the Netherlands; the second provides the family physician's concept of mental health and mental health services; the third deals with the training that primary care physicians receive in psychiatry, both at undergraduate and postgraduate level; and the fourth section takes a look at some of the research that has already been done in this field.

Although this symposium brought together nationals of two countries with markedly different health care systems, the first two sections of the book describe more vividly the differences and sometimes difficult relations between the two disciplines, rather than the national differences, which take second place. The boundary disputes between primary care physicians and mental health specialists, both of whom now regard 'psychosocial' as well as 'psychiatric' problems to be within their domain, are an underlying theme. The gatekeeping function of family doctors who determine which patients are referred to mental health services is criticised on the one hand as protectionist and on the other as denying patients (some of whom, in the family physician's opinion, do not require medical treatment at all) the right to a specialist opinion. It is concluded in several papers that there is a need to improve communication between the primary care team and mental health services, and suggestions as to how each might work with the other in their different locations are offered.

The largest section of the book is devoted to training issues, and several papers are devoted to describing education programmes which aim to improve communication skills – both between patient and doctor, and between the professionals themselves. There is also agreement on the need for much better training in psychiatry for family doctors.

The final section on research is the weak link in the book. Three dreary, only partially completed, descriptive studies are presented and leave one feeling rather dispirited as to how all the useful and valid comments and criticism from the earlier part of the symposium can actually be put into practice.

DEBORAH J. SHARP, *Lecturer in General Practice, United Medical & Dental School of Guy's & St Thomas' Hospitals, London*

Understanding and Treating the Psychopath. By DENNIS M. DOREN. Chichester: John Wiley & Sons. 1987. 246 pp. £30.95.

This is a sound and interesting book, clearly written by an author with first hand experience of a treatment situation which he calls "not hopeless, just difficult". Perhaps many psychiatrists are not sufficiently involved with psychopaths to find the book of great value, but forensic psychiatrists, and particularly probation officers, or prison officers in a treatment facility, would find it invaluable.

The first half of the book is a comprehensive literature review of the current major theories of psychopathy – role-playing deficiency (Gough), deficient conditioning (Eysenck), stimulation seeking (Quay), low critical arousal (Hare) – written in a style which often makes them easier to assimilate than the originals. The author gives his critical comments on each, but also attempts an eclectic integration. The second half of the book, in contrast, is then virtually devoid of references and reviews of other work and gives straightforward examples of the games psychopaths play in the attempt to control their environment and how the therapist might respond, rather after the style of a behaviourist or transactional analytic method.

It is very much a personal account of individual interactions with psychopaths, and one recognises only too well all the ploys, the projections, the traps and the torment. Just reading another's account of such gives the practitioner encouragement to persist. My only disappointment is that, in contrast to the widest review of the theoretical aspects, the treatment description is restricted to one style of client-therapist interaction. There is no mention of group, peer pressures, or therapeutic community, all of which can also help to share the load, arouse self-awareness, stimulate responsibility taking, and increase self-esteem.

J. STUART WHITELEY, *Consultant-Psychotherapist, Henderson Hospital, Surrey*

Reassessing Community Care. Edited by NIGEL MALIN. Beckenham: Croom Helm. 1986. 354 pp. £22.50.

As Community Physician at Hammersmith Hospital I used to pass Consultants, in the corridors, hurrying to their next ward round. "How is the community?" they would ask cheerily, but not await my reply. For psychiatrists who are hospital-bound but have time to open a book, Malin offers an answer, in this timely collection of essays on community mental health care. Much of the experience described is drawn from work with mentally handicapped people, but the ideas and proposals have contemporary relevance in a decade that may see the closure of several large mental illness hospitals. An authoritative essay by Val Reed on community nursing indicates the transition of community psychiatric nurses from 'medical handmaids' towards a greater autonomy in assessment and therapy. David Race gives a concise outline of normalisation theory, and Alan Tyne describes programmes for training in PASS, the detailed evaluation instrument derived from normalisation. Elsewhere there are useful descriptions of experience with group homes and rehabilitation projects. Nevertheless, in his opening chapter, Malin draws attention to the underlying structural problem of mental health care in Britain. Social services departments often have progressive ideas and would like to provide more community services, but the Government's policy of rate-capping Local Authorities directly inhibits these initiatives. Health Districts, on the other hand, often have considerable resources tied up in the large institutions, but there is professional resistance to change. Only a realignment of care philosophies between the two major services will overcome the impasse and refute the prophecy that community care is destined to fail.

MARK MCCARTHY, *Senior Lecturer in Community Medicine, University College Hospital, London*

Philosophical Medical Ethics. By RAANON GILLON. Chichester: John Wiley. 1985. 189 pp. £8.50.

In the past 30 years psychiatry has gone through something of a scientific revolution. It is no longer sufficient that we base our beliefs and management on intuition or experience. We are expected to defend our decisions, giving reasons and evidence for what we do.

Clinical practice is not simply a scientific enterprise; it is also a moral one. However, in general we are not expected to bring the same sophistication and rigour in our thinking to our moral decisions as we are to our scientific ones. Gillon, a general practitioner and philosopher, challenges this. In his opinion we need to be equally critical in thinking about both aspects of clinical practice.

This book is made up of 26 essays which originally appeared in the *British Medical Journal*. Because together they form a coherent whole they are, I think, more successful as a book than they were in weekly instalments spread over half a year.

Gillon has successfully achieved his two aims. The first is to argue that doctors should take moral philosophy seriously. The second is to give an introduction to medical ethics. In less than 200 pages, a clear outline is given of moral philosophy. The reader is introduced not only to the central topics such as utilitarianism, rights, and justice, but also to many of the detailed issues, for example to the principle of double effect, to the distinction between acts and omissions, and to the doctrine of ordinary and extraordinary means. These various principles and ideas are brought to bear on several problems of medical ethics, including abortion, paternalism, confidentiality, and (of particular interest to psychiatrists) consent.

This is an exceptionally good introduction to medical ethics, which can be read with pleasure, a chapter a night for a month (with weekend off), or it will serve well as a basic text for a seminar course, with several weeks devoted to each essay.

R. A. HOPE, *Clinical Lecturer in Psychiatry, Oxford University*

Handbook of Psychiatric Drug Therapy. By STEVEN E. HYMAN and GEORGE W. ARANA. Edinburgh: Churchill Livingstone. 1987. 173 pp. £12.95.

This is a well laid out paperback that aims to be a handbook of psychiatric drug treatment. It succeeds in its aims of being a useful introduction to psychopharmacology and of providing help in careful and effective drug prescription. At the end of each chapter a few recent references are provided, but these are not comprehensive reading.

The two-page introduction to psychopharmacology contains sensible principles to guide drug therapy in psychiatry (e.g. be sure to allow for a full trial of an adequate dose before changing treatment, keep the regimen simple). Chapters 2, 3, and 4 cover antipsychotics, antidepressants, and lithium respectively. Chapter 5 describes carbamazepine and other anticonvulsants used in psychiatry, while chapter 6 tackles the benzodiazepines. The final chapter is entitled "Other agents: psychostimulants, beta adrenergic blockers and clonidine". All the chapters use a similar format and cover chemistry, details on metabolism, blood levels, absorption and mechanisms of action of the drug, side-effects (including mechanisms), indications for prescription of the drug, therapeutic usage, and consideration of populations to whom special attention needs to be given. There is also a consideration of the treatment of overdosage with the drug.

It needs to be borne in mind that this is an American book aimed at the United States market, and therefore only considers drugs available for prescription there. Thus, no consideration is given, for example, to the use of chlormethiazole, mianserine, or lofepramine. In addition, there are drugs mentioned which are not on prescription in this country, such as thiothixine, molindone and loxapine. Where diagnoses are considered these are based on DSM–III, but this should not nowadays prove a great problem to the British readership.

The authors also sensibly exclude consideration of drugs with only historic interest, such as some of the older sedatives and hypnotics. One particularly useful feature of the book is a table which provides dose equivalences for the anti-psychotics and expected side-effect profiles.

I found the book quite readable and a fairly useful handbook, but the fact that it is not fully comprehensive for a British readership and relatively expensive for such a small book might reduce its popularity in this country.

ANNA HIGGITT, *Locum Consultant Psychiatrist, The Maudsley Hospital, London*

Sexuality and Medicine. Volume 1: Conceptual Roots. Edited by EARL E. SHELP. Dordrecht, The Netherlands: Kluwer. 1986. 271 pp. £38.95

In a foreword to this volume Masters & Johnson state that this book "is an excellent example of how to present material of sexual content to the health care field". They further comment that the strength of the volume resolves around the material of ethical consideration and that the chapters on philosophical approaches to human sexual behaviour provide an additional dimension to ethical considerations. I find those opinions to be balanced and an accurate assessment of a thought-provoking volume.

The volume consists of two sections. The first largely relates to the more clinical aspects of human sexuality, and in particular the changing concepts regarding the treatment of sexual problems. Suppe's essay ("Medical and psychiatric perspectives on human sexual behaviour") concludes, "If medicine and psychiatry are to regain their lost authority over sexuality they had best recognise the truth of Kinsey's insight, put to a final rest the Victorian "theory of normal love", and commit themselves to practice rooted in and constrained by scientific research meeting the highest contemporary standards. Such a medicine and psychiatry of sexuality will be quite unlike what we are accustomed to. But what authority they enjoy will then become as legitimate as their prior authority has been unscientific and fraudulent".

The second edition, mainly of a philosophical nature, concentrates the reader's attention on matters not necessarily considered of primary importance by those individuals involved in the treatment or counselling of those with sexual difficulties. It is impossible to comment in detail on the many essays in this section, but I draw attention to Solomon's essay "Heterosex", written with clarity and a sense of humour. He concludes: "If medicine seeks to understand heterosex, physicians should study poetry, not just physiology".

Breggin, in the final essay ("Sex and love"), states: "A sexual dysfunction is a life dysfunction and a successful sexual life is inseparable from a good life".

I found this volume informative, thought-provoking, and a valuable contribution to the literature on human sexual function and dysfunction.

H. B. MILNE, *Emeritus Consultant Forensic Psychiatrist, Bradford*

Humor and Psychotherapy. By THOMAS L. KUHLMAN. Illinois: Dow Jones-Irwin. 1984. 129 pp. $22.50.

"I don't believe in growth through pain" said Peter Cook, "I would rather be stunted by pleasure". Both psychotherapists and their patients are familiar with the proposition that through suffering we can arrive at maturation. This book is part of a growing literature which proposes not only that humour and the pleasurable experiences associated with it may be an acceptable part of the therapeutic process but that humour may even promote that process. Or, in Kuhlman's words, humour may serve "as an insight vehicle" or as a valuable "intervention tactic during the psychotherapy hour". If you can take this linguistic style then this book is a good read. It provides a matter-of-fact account of the increasing acceptance of varieties of humour as a useful part of the communication between therapist and patient as well as tracing the history of this development. There are chapters relating to the acquisition of insight and the development of functional detachment to the individual's capacity for humour. Far from stunting growth, it seems humour may enhance it. Nonetheless, the risks and dangers involved are also discussed and the author is to be commended for his honesty in recounting the history of a patient who terminated therapy after "a quip" which the author made in the seventh session.

Humour does not always travel well. The experience of humour often seems peculiarly subjective, and definitions of humour can be idiosyncratic. There are some good jokes in this book, but the verbal transcripts of therapeutic sessions incorporating humour seem singularly unfunny. Humour is a tricky subject to pin down.

The task-orientated tone of the book may derive from the author's training as a clinical psychologist and his current position as Unit Chief of the Maximum Security Aggression Unit at Mendota Mental Health Institute in Madison, Wisconsin. This book will not convert the sceptics, but for those therapists who wish to feel respectable when they take humour seriously it will provide much-needed encouragement.

JANE CAMPBELL, *Associate Therapist, Warneford Hospital, Oxford*

Clinical Empathy. By DAVID M. BERGER. Northvale, NJ: Jason Aronson. 1987. 297 pp. £27.50.

This book raises many interesting issues which warrant close attention. Berger explores the concept of empathy from the two psychoanalytic schools of self-psychology and classical psychoanalysis. In terms of these two perspectives, the therapeutic value of empathy respectively resides in promoting growth and self-understanding in the patient. Empathy is defined as the process by which the therapist knows what the patient is feeling emotionally, particularly as this is related to past relationships.

The book falls into three parts. The first provides a theoretical discussion of the concept. The chapters that follow may be the most rewarding for the practising clinician, in that they illustrate with clinical examples the ways in which empathy may be enhanced. The concluding section discusses the role of empathy in other aspects of therapy, such as supervision and termination.

The author shows how insight may be fostered by the openmindedness of the therapist in oscillating between putting himself or herself in the position of the patient and stepping back and reflecting on how the patient's behaviour may be related to the past. This book deserves the careful attention of psychotherapists.

DUNCAN CRAMER, *Lecturer in Social Psychology, Loughborough University of Technology*

Dream Life, Wake Life: The Human Condition through Dreams. By GORDON GLOBUS. Albany, NY: State University of New York Press. 1987. 203 pp. $34.50 (hb), $10.95 (pb).

I found this a most enjoyable book, and recommend it to anyone with an interest in the philosophy of mind. Globus attempts an analysis of the human condition through the study of dreaming. His arguments lead, step by step, to unusual and frightening conclusions.

First, he argues against the notion that dreams are composed from memory traces of concrete waking experiences. He points out that many events in dreams have not and could not have actually happened. Dreams, therefore, cannot be a collage of memories but must be newly created experiences. At this point I was drawn to his conclusion that we have "the capacity for infinite creativity".

The next step proved more difficult to accept. He suggests that dream life and wake life are indiscernible. He says there is no difference in our unreflective experience of the life that we lead in our dreams and the life that we lead while awake. As we experience them, both seem to be really happening – so much so that philosophers such as Descartes have wondered how they could prove that they were awake and not in a dream.

Globus goes on to argue that if dreams and waking consciousness are indiscernible, then they must be determined by the same mechanisms. That is, they are both formatively creative. Our awake life is dreamed up. We don't look out at the world and perceive it as it is. Our consciousness is created from within. "In each case, dreaming and waking, the monadic organism generates a life-word, *de novo*, by abstract means". Is this disturbing conclusion fanciful? Much rests on whether or not dreams and waking consciousness are discernible in the way that Globus describes. I was not convinced.

He goes on to propose a model of the brain capable of such formative creativity and to suggest how its images may be linked to input from the outside world. The model is based on holography and the mechanisms of the immune system – a refreshing change from the idea that the brain is a sophisticated computer.

Globus has produced a challenging book based on ideas from psychoanalysis, linguistics, philosophy, and cognitive psychology. There is much to disagree with, but it does make one think again. He argues for human creativity. His book shows that he is endowed with a large dose of it.

C. R. WHYTE, *Consultant Psychotherapist, Humberstone Grange Clinic, Leicester*

Variant Sexuality: Research and Theory. Edited by GLENN D. WILSON. Beckenham: Croom Helm. 1986. 268 pp. £25.00.

I looked forward to reviewing this book, which attempts to explain why some men, seemingly well-adjusted, indulge in sexual activities judged by society to be variant. A book which updates and edits the few empirical studies and scarce systematic investigations in this area must be welcome. The book is, however, disappointing. You have to be a dedicated reader to finish it, especially when it gets into technical, mathematical, or anthropological argument. At the end the reader remains no wiser as to why people behave in this way. I had hoped that the authors would mention the clinical or therapeutic implications of their findings, but they encourage a sense of therapeutic nihilism by implying that these people cannot be helped therapeutically. This sad state of affairs reflects our deficient knowledge of the subject. Extensive research is needed.

WAGUIH R. GUIRGUIS, *Consultant Psychiatrist, St Clement's Hospital, Suffolk*

The Borderline: Current Empirical Research. Edited by THOMAS H. MCGLASHAN. Cambridge: Cambridge University Press. 1986. 116 pp. $15.00.

This little book is part of a new American Psychiatric Series, designed to bring selected material from the APA Annual Meetings to the attention of a wider audience (topics covered in similar publications include premenstrual syndrome and affective disorders in the elderly). It contains five chapters covering such areas as diagnosis, biological markers, outcome, transitional objects, and the relationship between psychodynamics and symptoms.

The individual papers are of interest, and should be read by researchers in the field. Together they remind one yet again of the persistent confusion in this area between 'borderline' as a specific psychological constellation, and 'borderline' as a phenomenological diagnosis. The case for the latter may be waning. Unlike many conference proceedings this book is attractively packaged and well printed, but nevertheless suffers from the common problems of appearing very late (three years!) and being very expensive. Psychiatrists with access to the major journals may not need to buy this book.

MARK BERELOWITZ, *Senior Registrar in Child Psychiatry, The Maudsley Hospital, London*

Psychiatry in Medical Practice. By DAVID GOLDBERG, SIDNEY BENJAMIN and FRANCIS CREED. London: Tavistock Publications. 1987. 322 pp. £12.95.

This handsomely produced paperback might be called the 'Manchester text'. It was written by three senior academic psychiatrists, with contributions from six other academic and NHS colleagues. Part 1, the clinical approach to the patient, includes history and mental state, concepts of diagnosis and aetiology, a well-written long chapter on treatment, and a particularly good guide to the formulation. Part 2 describes the syndromes of psychiatric disorder and their treatment. Part 3, concerned with disorders peculiar to stages of the human life cycle, covers mental retardation, child and adolescent psychiatry, sexual and reproductive disorders, and psychogeriatrics. Part 4 consists of two chapters: an interesting one on psychiatry for the houseman, and another on legal aspects. Finally, there is the card, a glossy five part *aide-mémoire* that includes the CAGE questionnaire, a short mood scale, the Newcastle dementia scale, and the headings of the history and mental state.

The book is aimed at the newly qualified doctor as well as the medical student, and claims to offer more guidance on treatment than the usual undergraduate text. It also claims to offer an up-to-date account of the sciences basic to psychiatry, neurochemistry (mostly pharmacological), epidemiology (well done, as you would expect from the senior author), and psychology (not very extensively dealt with). These topics are not given chapters to themselves, being discussed where appropriate in the text.

The style is generally terse but always clear, with illuminating clinical illustrations. The order in which topics are considered is unusual and interesting. The book is stimulating, and students will like it.

J. L. GIBBONS, *Professor of Psychiatry, University of Southampton*

Forty Two Lives in Treatment: A Study of Psychoanalysis and Psychotherapy. By ROBERT S. WALLERSTEIN. New York: The Guilford Press. 1986. 784 pp.

This large tome is the 69th publication which has come out of the Meninger Foundation's Psychotherapy Research Project. In the preface to the book the project is described as probably the most comprehensive as well as the most ambitious psychotherapy research programme ever conceived and carried out. From the outset it must be stressed that the Meninger Foundation is a psychoanalytic institution, that the project is concerned exclusively with psychoanalysis, and that to fully appreciate the book the reader needs to be well versed in, and sympathetic towards, the theory and methods of psychoanalysis.

The 42 analysands, upon whom the project is based, were divided, in a non-random allocation, into 22 who were to receive classical psychoanalysis, involving the establishment and ultimate resolution of a regressive transference neurosis, and 20 who were to receive expressive or supportive psychoanalytically-based psychotherapy which did not evoke a full transference regression. In the event, six of the original psychoanalysis patients were subsequently transferred to one of the two psychotherapy categories and a further six received only modified psychoanalysis. The outcomes of the different treatment modalities were broadly similar, approximately 40% of each being reported as having made "really good improvement".

The author of the book was one of the originators of the project, and he has been associated with it throughout. He has an overall grasp of the project and a familiarity with each of the 42 patients, to whom he makes recurrent reference. Here the reader is at a disadvantage, and can only gradually accumulate a picture of each patient by working through the issue-related chapters.

The study was intended to be 'uncompromisingly naturalistic' in that neither the analysands nor the analysts knew at any time throughout the course of therapy that it was in progress. The patients, who were amassed between 1954 and 1958, were considered to be difficult and challenging, requiring long-term therapy. Duration of treatment ranged from 7 months to over 10 years; at the time of publication, 23 years after the inception of the project, four of the patients were still involved in therapy. By this time eight patients were known to have died, six from "mental illness related causes".

The author considers this to be "the most intensively studied and systematically documented large collection of psychotherapy cases extant". Each patient is reported to have a 'case study' of 50–70 pages of typing summarising history, diagnosis, treatment, and outcome, and the principal objective of the project would appear to be to examine carefully why the treatments that worked worked and why those that failed failed. It would be reasonable to conclude that this meticulous teasing out of the strategies employed in the treatment of this small, albeit heterogenous, sample of patients has contributed to an understanding of what works best with whom. This would indeed appear to be one kind of science.

JOHN BIRTCHNELL, *Scientific Officer and Senior Lecturer, Institute of Psychiatry, London*

Altruism and Aggression: Biological and Social Origins. Edited by CAROLYN ZAHN-WAXTER, MARK E. CUMMINGS and RONALD LANNOTTI. Cambridge: Cambridge University Press. 1987. 337 pp. £30.00, $39.50.

Of the 12 chapters in this multi-author book, four deal with the "biological, sociobiological and ethological approaches to the study of altruism and aggression" and seven with the "development, socialisation, and mediators of altruism and aggression in children". The concluding chapter helpfully summarises the problems of research in these fields. The fact that this book, first published in 1987, is stated to be "the outcome of a conference held in 1982" (at Bethesda, Maryland) should not embarrass the reader, for some ten percent of the references are to publications in 1983 or later.

It might perhaps be a criticism that there is no formal or agreed definition of the two terms which form the title of this book. The meaning of 'aggression' is taken as obvious – but it is not made clear whether selfishness or competition are forms of aggression. *'Altruism'* "is commonly defined as regard for, or devotion to, the interests or welfare of others"; and the term is consistently used in the sense of co-operation, helping, or sharing. But this usage is quite distinct from that of the sociobiologists, for whom altruism typically means 'self-destructive behaviour performed for the benefit of others'. The difference in meaning seems to diminish the revelance of sociobiology to the problems discussed here.

No one would deny that the aim of such studies in child psychology is a worthy one, for the greater our knowledge of the development of competitive and co-operative behaviour, the better will the forces that make for hate or love, crime or service, war or peace, be understood. But the present book is evidence of the difficulties of such study. That most of the field work has been limited to white, middle-class American families is a minor criticism. The real problems lie in the elusive nature of the concepts and in the complexity of longitudinal studies. Thus, the expression of altruism and aggression may take different forms at different ages; the distinction between selfishness and self-interest may be hard; and the tendency of some children to internalise their emotions may make facial expression an unreliable guide to the detection of empathy.

No doubt because of such difficulties, there has been little consensus of finding. One finding is that the basic pattern of a child's aggressivity is present at an early age and tends to remain stable through childhood, especially in boys. Genetic factors are not discountenanced here; but, as one contributor observes with regard to the expression of emotion in boys and girls, sexual stereotyping probably begins at the moment of birth. The emphasis of the book is on the social causes of behaviour and on the prospects of special training to guide behaviour into acceptable channels.

EDWARD HARE, *Honorary Consultant Psychiatrist, The Maudsley Hospital, London*

Measuring Emotions in Infants and Children (Vol. 2). Edited by CARROLL E. IZARD and PETER B. READ. Cambridge: Cambridge University Press. 1986. 277 pp. £27.50, $39.50.

Many clinical decisions in child psychiatry require that a judgement be made on the emotional reactions being shown by an infant or young child. This can be a crucial issue when an opinion is being given on, for example, whether a child should remain with foster parents or return to its family of origin. However, our knowledge of the expressions of emotions by the under fives is limited, and any judgements must be cautious. This book is to be welcomed, as is any work in this field. Volume I, published in 1982, presented research completed by 1979. This book brings the field up to date. There are four sections: physiological approaches, facial and vocal expressions, mother/infant interactions, and the conceptualisations of emotion. Much of the work is methodological and is intended for future researchers, but throughout the clinician will find much of interest and importance. In the physiological field I was excited by the findings of differential right/left frontal lobe responses to positive and negative emotions in ten-month-old infants.

In the cognitive field, the ability of children as young as three to accurately differentiate and undertake a wide range of emotions is of importance. Child development research is progressing rapidly and becoming highly sophisticated. It is essential that these findings be fed into the clinical field, and equally essential that relevant clinical questions be fed back to the research teams.

This book would be a useful addition to a child psychiatric library.

STEPHEN N. WOLKIND, *The Maudsley Hospital, London*

Models for Mental Disorder: Conceptual Models in Psychiatry. By PETER TYRER and DEREK STEINBERG. Chichester: John Wiley. 1987. 118 pp. £6.95.

The authors have tried to draw together the various ways of conceptualising mental disorder. They identify a disease model, psychodynamic model, behavioural model, and social (environmental) model, and give an account of the advantages of each. They then describe their solution to the limitations of using only one of these models by means of their 'correlative model'. This 'eclectic's charter', as they put it, allows each of the four models to be used sequentially, or perhaps together, so as to obtain the fullest understanding of the person's difficulties and then the best therapeutic methods to employ.

The descriptions of the models, illustrated by Steinberg's engaging drawings, are clinically based and can help the student, confused by abstract and sometimes acrimonious talk of rival theories, to understand what these different approaches have to offer. The book is written in plain language, yet is detailed enough to be useful to students and postgraduates in medicine and the social sciences.

It is a valuable book in that it indicates that there is no essential incompatibility between the models, merely that they have their uses at different times and in different clinical situations. What matters is that clinicians *know* in which conceptual framework they are working at any given time, and that they do not allow themselves to believe that any one model contains the whole truth.

GLIN BENNET, *Consultant Senior Lecturer, University of Bristol*

Brain Systems Disorders and Psychotropic Drugs. By HEATHER ASHTON. Oxford: Oxford University Press. 1987. 547 pp. £40.00.

In the preface the author rightly chides those who prescribe psychotropic drugs and yet fail to appreciate the underlying brain systems on which they act. What follows is a valuable account of just those systems. There are five main divisions: the first three concern arousal and sleep, reward and punishment, and learning and memory, and then follow two sections on psychiatric disorders, one concerning mania and depression, the other schizophrenia. For each the anatomical, physiological, and biochemical/transmitter substrate is elucidated, followed by a discussion of the drugs that act on the structures in question. In the case of the 'reward and punishment', for example, alcohol and illicit compounds that have an effect are also discussed. It is pointed out that some compounds act on only one transmitter system and others have multiple effects. The author appreciates that here, as elsewhere, there is overlap and interaction, but as the book was first conceived as a teaching vehicle for undergraduates this is acceptable. What emerges, however, is a well-written book of appropriate length with 86 pages of bibliography, useful for a much wider audience. All practising psychiatrists can read it with profit, and it is a good reference book. Sadly, it may be too expensive for all those who would benefit. Arm-twisting of librarians is suggested!

D. F. SCOTT, *Consultant Neurophysiologist, The London Hospital*

Child Psychiatry: A Developmental Approach. By PHILIP GRAHAM. Oxford: Oxford University Press. 1986. 463 pp. £25.00 (hb), £12.50 (pb).

When I received this book, I must admit my initial reaction was: "Do we really need another introductory text in child psychiatry?" (thinking of the contributions made by Michael Rutter, Sula Wolff, Helen Connell, and most of all Philip Barker, whose *"Basic Child Psychiatry"* is now in its fourth edition). Graham states in his preface that he intends the book to be of use to all doctors dealing with children and their families, but especially to paediatricians and psychiatrists in training, and it seems to me that this goal is admirably realised. It is laid out in a comprehensive and systematic way, and the style is clear, pragmatic, and wholly readable.

In keeping with the subtitle (*'A developmental approach'*), the largest section of the book deals chronologically with various aspects of development: pregnancy, delivery and the neonatal period, feeding and growth, the development of social relationships, etc. There are sixteen different sections, each beginning with a review of the normal and moving on to separately headed topics or problems. Thus, the section on emotional development includes school refusal, depressive disorders, and suicide and attempted suicide, and that on sexual development includes anomalies of gender role and sexual behaviour, and pregnancy in schoolgirls. The first three chapters of the book are concerned with an overview of the subject, including classification (both the ICD–9 and DSM–III multiaxial approaches) and prevalence of psychological problems, the principles of assessment, and a review of family influences and parenting disturbances. The long chapter on development is followed by a fairly short one on specific psychiatric syndromes, picking out psychotic, hysterical, and obsessional disorders. In some respects, this seems the least satisfactory section of the book. It is oddly placed, and these particular diagnostic categories may seem to have been chosen rather arbitrarily to non-psychiatrist readers. It might have been illuminating to introduce the chapter by emphasising that these are often disabling conditions and more narrowly the province of psychiatrists than of similar other professionals.

There follow two chapters on psychosocial aspects of physical disorders, which should be particularly helpful to trainees without paediatric experience. The first and shorter of these is on general issues, such as hospitalisation and the care of the dying child; the second goes systematically through the range of specific physical conditions. The eighth chapter covers treatment approaches briefly but clearly, and it is here that the only illustrative case descriptions in the book are to be found. (It is of some comfort too that not all the cases described were unqualified therapeutic successes!).

Next comes a helpful chapter on children's services in general, clarifying the inter-relationships between different professionals and their services and pointing up the similarities and differences and the areas of overlap. The last, all too brief, chapter is on prevention. Each chapter ends with a short list of suggestions for further reading and there is a comprehensive (over thirty pages) reference list at the end of the book.

This is a splendid but very down-to-earth introductory text which, in spite of my initial reservations, I must agree fulfills the specific need identified by its author. I have already taken the opportunity of recommending it wholeheartedly to different groups of community physicians and GP trainees to whom I have lectured recently.

PATRICIA AINSWORTH, *Lecturer in Child and Adolescent Psychiatry, University of Manchester*

Object Relations, the Self, and the Group: A Conceptual Paradigm. By CHARLES ASHBACH and VICTOR L. SCHERMER. London: Routledge & Kegan Paul. 1987. 313 pp. £25.00.

The authors of this book have tried to create a synthesis between individual and group therapy. Psychoanalysis was originally only concerned with the structure of the psyche and its disturbances, and many psychoanalysts have remained sceptical of the attempts of group therapy to treat people within and as a group. On the other hand, Foulkes, the originator of group analysis in this country, after recommending a combination of individual and group therapy in the beginning, emphasised in his later writings the capacity of group analysis to deal with most kinds of disturbance. In this way, the gap between two approaches grew.

More recent developments within psychoanalysis focused on the inter-psychic elements in human growth. Object relations theory and self psychology see the interaction between mother and child as crucial for the child's development. One could say that already mother and child form a sort of mini-group with its own kind of dynamics. At this point the barrier between the intra-psychic and the inter-psychic breaks down, and the way is open for an attempt to relate individual and group therapy to each other.

Within group therapy the authors distinguish between three 'systems': the intra-psychic, the interactive (the relationship between the individual group members) and the group-qua-group. All three systems interact with each other in a great many different ways, and these are plotted in great detail in a 'group analytic grid'. It is impossible to do justice in a short review to this fundamental and scholarly contribution to an important area of theory and practice.

HANS W. COHN, *Group-Analytic Society, London*

Criminal Law and Psychiatry. By D. POWER and D. H. D. SELWOOD. London: Kluwer Law Publishers. 1987. 265 pp. £50.00.

Power is a former senior prison medical officer, and Selwood a member of the army legal service and a crown court recorder. The main part of the book comprises a number of chapters on the association between crime and sexual deviation, psychosis, psychoneurosis, mental impairment, and psychopathy. It opens with a clear account of the elements of crime, a section on the law of homicide, and a description of exemptions from criminal responsibility. The first chapter concludes with a discussion on chromosomes, which is both misplaced and has paragraphs of the text transposed. The references to the chapter on young offenders have been omitted altogether.

Other chapters which discuss social factors in crime, young offenders, and illicit drug-taking are notable for the authors' anecdotal style and dubious moral judgements. The references are almost wholly out-dated: for example, the major studies on psychosis and crime, and on delinquency, are completely ignored.

The book is overly concerned with the bureaucracy which prison medical officers suffer, and the final chapter on military psychiatry involves such unlikely bedfellows as indoctrination, brainwashing, battle fatigue, exhaustion, assassination, and urban guerilla warfare.

Pages 21–26 contain numerous errors. The prosecution cannot accept "strong evidence" of unfitness to plead, since the matter is always decided by a jury. The authors state that restriction orders are always added to hospital orders in homicide cases and that these Section 37/41 Mental Health Act 1983 cases go to special hospitals. Both assertions are incorrect.

Page 23 refers to "mental responsibilities" where it should read "responsibility". On the same page it states that three persons were tried for murder in 1963, wheras the actual figure is nearer 300. The reference to "statistics for England and Wales" should read "Criminal

Statistics". On page 24 'mental responsibility' is applied only to the exercise of will-power, but the judgement in the case of R. *v* Byrne [1960] 3 All ER 1 states: "The expression 'mental responsibility for his acts' points to a consideration of the extent to which the accused's mind is answerable for his physical acts which must include a consideration of the extent of his ability to exercise will-power to control his physical acts".

There are two major errors on page 25: that homicide committed during the course of acute psychotic illness would come within the McNaughton rules; and that psychopathy coming within the Mental Health Act 1983 definition would amount to diminished responsibility.

The publishers' blurb states that the book is the first serious attempt to counteract misunderstandings by endeavouring to bridge the gap between the criminal law and psychiatry. For those who use this text, misunderstandings will be multiplied and, following the allegory, the bridge is used at the peril of those attempting to cross.

PAUL BOWDEN, *Consultant Psychiatrist, Maudsley Hospital, London*

Issues in Diagnostic Research. Edited by CYNTHIA LAST and MICHEL HERSEN. New York: Plenum. 1987. 349 pp. $45.00.

This book would not have been published if DSM–III had not been invented. One of the main results of the introduction of DSM–III has been much greater interest in the diagnostic process. This volume is therefore a timely look at the methodology of diagnostic assessment and broader issues about its aims, achievements, and pitfalls.

The first chapter, by Theodore Millon, is 84 pages long but represents a distillate of the principles of classification that could easily have been expanded to a book in itself. It is a masterly review of different approaches to classification and emphasises the modesty of the true taxonomist. However successful our diagnoses appear to be, we must "bear in mind that these labels and transformations are not 'realities' ". The rest of this section is concerned with general issues in classification, and include a particularly useful discussion by Grove of methods of recording reliability of psychiatric diagnosis. The second section is concerned with methodological issues, the particular problems of making psychiatric diagnoses during development and over a lifetime, and biological and genetic approaches. The latter are particularly valuable because they point to other ways of achieving diagnosis, now or in the future; their advantage is that they do not depend on the vagaries of clinical symptomatology. The third part of the book is less well integrated, and discusses diagnostic problems with special subjects. These include child psychiatry, where diagnosis still appears to be much less important to its practitioners than in other parts of psychiatry, and an interesting chapter on computer-generated diagnosis by Headlund & Biewig.

Although this book is primarily for the taxonomist and research worker, it would be of value for others to read to see the directions in which psychiatry is going. The time has not yet come whereby a clinician's diagnosis is likely to be independently validated by other measures, but there are glimmerings of this on the horizon. We are all diagnosticians now.

PETER TYRER, *Consultant Psychiatrist, Mapperley Hospital, Nottingham*

Self and Identity: Psychosocial Perspectives. Edited by KRYSIA YARDLEY and TERRY HONESS. Chichester: John Wiley & Sons. 1987. 332 pp. £28.00.

This book is a curious mixture of psychology, psychiatry, and sociology with sociology as the dominant perspective. It takes the problem of the self, one of the key issues in modern philosophy, and explores the theoretical and practical implications of the concept for sociology and psychiatry.

Like any collection of essays, some of them, such as the analysis of Eastern concepts of the self, are excellent, while others are at best pedestrian. Psychoanalytic concepts of identity and object relations are well reviewed, but the contribution of the existentialists and existential analysts such as Victor Frankl and Rollo May are, for unexplained reasons, ignored.

This is primarily an Academic work with a capital A, rich in references but rather short on insights and practical strategies for clinical practice. The academic, the research worker, and the armchair theoretician will find the depth and width of scholarship in this book a rich source. The practicing clinician, however, will probably find it rather arcane and alien to the world of patient care.

L. RATNA, *Consultant Psychiatrist, Barnet General Hospital, Herts*

The Psychological Experience of Surgery. (Wiley Series in General and Clinical Psychiatry). Edited by Richard S. Blacher. Chichester: John Wiley & Sons. 1987. 236 pp. £30.45.

This is a valuable collection of essays, which I would recommend highly to liaison psychiatrists and, more particularly, surgeons and other professionals concerned with the impact of surgery on patients. Written by twelve authors, it has the advantage of avoiding monotony of style; it varies from the beautifully written chapter on denial, with nine general references, to the comprehensive chapter on superobesity with 98. There is a tendency, however, for the theme of surgical 'trauma' to be repetitious without acknowledging the fact that many patients look forward to surgery as an end to pain, discomfort, or the invasion of malignancy.

The book includes many short case histories which make the text vivid, although the emphasis on individual psychotherapy tends to be a little dismissive of the value of the diagnostic psychiatric interview and physical treatments. The last chapter redresses the balance somewhat by underlining the need for rapid goal-directed psychotherapeutic intervention. The book should contain more emphasis on the strategies used to improve the ward milieu, communication between staff and patients, and the morale of staff. Equally, perhaps, the importance of understanding the premorbid personality traits should be stressed, because these so often predict the patient's attitude to the operation and contribute to his post-operative satisfaction.

These are minor strictures on an otherwise very readable and useful book.

BERNARD ADAMS, *Consultant Psychiatrist, University College Hospital, London*

Studies in Neuropsychology: Selected Papers of Arthur Benton. Edited by L. COSTA and O. SPREEN. Oxford: Oxford University Press. 1986. 351 pp. £36.00.

Professor Benton has not published a general comprehensive work on neuropsychology; his vast contribution to the field remains scattered throughout neurological and neuropsychological journals. This welcome volume contains seminal contributions that Benton and his collaborators have made to neuropsychological investigation. It represents, however, only a fragment of his output.

The book has been divided into nine sections, each dealing with a specific neuropsychological problem. Aphasia is the topic of the first section; the two papers in this section present a historical review touching on early descriptions of aphasia and the contribution of Freud to the interpretation of aphasic disorders. Sections II and III contain articles dealing with cerebral localisation and the appraisal of the method of double stimulation in which the problem of sensory extinction is discussed. Constructional apraxia and spatial abilities is the focus of section IV, and section V is devoted to the topic of reaction time and brain disease. The so-called 'Gerstman syndrome' is the subject of three articles in section VI, and the problems of hemispheric dominance and vision are discussed in section VII. The last two sections have a more direct relevance to the psychiatrist. One deals with the topic of developmental neuropsychology, which includes Benton's seminal paper 'The concept of pseudofeeblemindedness' (1956) in which a then-popular term is carefully analysed and criticised. The final section contains two papers useful in the psychiatric clinic: "Problems of conceptual issues in neuropsychological research in ageing and dementia" (1984), and "Normal observations on neuropsychological test performance in old age" (1981).

The collection shows many facets of neuropsychology, and offers useful guidance in testing and test design. The historical emphasis of most of Benton's articles provides a useful perspective of the history of neuropsychology.

MARIA A. WYKE, *Senior Lecturer in Neuropsychology, Institute of Psychiatry, London*

The Clinical Roots of the Schizophrenia Concept: Translations of Seminal European Contributions to Schizophrenia. Edited by J. CUTTING and M. SHEPHERD. Cambridge: Cambridge University Press. 1987. 238 pp. £27.50.

Whoever writes the first history of psychiatric anthologies in English will have to observe that, since the earlier centos by White, Goshen, Hunter & McAlpine and Hirsch & Shephard, the compass of these useful (albeit non-historical) publications has gone from the general to the particular. The same historian will also have to say that this change has made things harder for would-be anthologists.

The old anthologies assumed little historical knowledge; to produce a good one it was sufficient to rummage one's library and choose the right morsels. 'Committed' anthologies, on other hand, demand such knowledge, as inclusion criteria entail a historical hypothesis. Old anthologies were difficult to review (omissions could always result from whims or quaint preferences); the new ones can be judged historically.

The book under review offers an *aperçu* of the history of schizophrenia. The material is heavily edited, but it is possible to gain an idea of the views involved. The translations are competent and clear. Because of its guiding historical hypothesis, work by Kraepelin, Bleuler, and their clientele is mostly considered. The inclusion of Kleist is more imaginative, but Wernicke is not mentioned nor indeed Meynert, particularly his work on amentia. One can understand why Kahlbaum's *Catatonia* has been left out (it is available in English translation), but not why his superb 1890 paper on 'Heboïdophrenie' has been omitted, nor why Daraszkiewicz's classic monograph on 'Hebephrenie' and Jung's work do not get a mention.

The most glaring omission concerns French works. It feels often as if inclusion has been guided more by availability than by historical intelligence. For an analysis of the earlier vicissitudes of dementia praecox in France (which, incidentally, the Germans followed with worried amusement) would have shown that during the first decade of the current century the protagonists were Marandon de Montyel, Mongeri, Parant, Monod, Deny, and Roy, and during the second Mairet and

Margarot, whose superb monograph on 'démence précoce' appeared in 1920.

But it would be unreasonable to demand that this modest work, edited by clinicians, should meet high historical standards. As it is, it offers enough pabulum for younger colleagues to feed on for many a winter night. It should therefore be included in all psychiatric libraries.

G. E. Berrios, *University Lecturer in Psychiatry and Consultant Psychiatrist, University of Cambridge*

MCQ Examinations in Psychiatry. By John M. Eagles and David A. Alexander. Aberdeen: The Aberdeen University Press. 1986. 263 pp. £10.95.

Few trainees approaching the MRCPsych examinations will be able to resist this book, which contains 300 multiple choice questions. The authors have compiled five MCQ papers based on the format of the membership examination (pre-1987) and supplied answers, referenced to support their accuracy. Apart from having a good factual knowledge, knowing when to guess is the most crucial component of good MCQ technique. Rather than offer advice on this issue, the authors invite readers to make answers with various levels of confidence (certain, doubtful or guess), and from the results to draw up their own individualised codes of guessing practice.

MCQ examinations test the breadth of the candidates' knowledge; this book aims to stimulate 'revision' as well as sharpen technique. It should continue to serve this purpose despite the recent changes in the format of the membership examination.

Paul Lelliott, *Honorary Lecturer, Institute of Psychiatry, London*

The Biochemical Basis of Neuropharmacology (5th ed.). By Jack R. Cooper, Floyd E. Bloom and Robert H. Roth. Oxford: Oxford University Press. 1986. 400 pp. £25.00 (hb), £12.50 (pb).

This is the fifth and much revised edition of the most popular introductory text on the biochemical basis of neuropharmacology, by three eminent neuroscientists. It distils the enormous literature on the biochemistry and physiology of the central nervous system with emphasis on neurotransmitters in relation to the drugs which specifically affect these functions. Current research trends in the neurosciences, such as the use of molecular genetics, are well synthesised with a critical appraisal of patterns of research design and the procedures used to obtain data. Two chapters on molecular neuropharmacology and on the modulation of synaptic transmission have been added to the classical chapters on cellular foundations of neuropharmacology, metabolism in the central nervous system, and receptors and the major chapters on specific neurotransmitters including acetylcholine, catecholamines, and neuroactive peptides. The chapter on modulation of synaptic transmission exposes the simplistic conception of point-to-point transmission between pre-synaptic and post-synaptic neurones, and offers a framework for understanding the complexity of neurotransmitter/neuromodulator/neurohormone interactions and the flexibility necessary for intergrating neurochemical with behavioural mechanisms. The authors have adhered to their original aim of presenting authoritative overviews with a few selective references rather than large bibliographies. They have also maintained the lively and entertaining style in which previous editions had been written: an earlier edition engaged the writer in what appeared to be the hitch-hikers guide to the galaxy of neurotransmitters. It is an essential reading to students of neurosciences, and it should provide a working knowledge of the subject for psychiatrists in training.

M. T. Abou-Saleh, *Senior Lecturer in Psychiatry, Royal Liverpool Hospital*

Understanding Mental Retardation. By Edward Zigler and Robert M. Hodapp. Cambridge: Cambridge University Press. 1986. 292 pp. Price £27.50 (hb), £9.95 (pb).

This book unashamedly sets out to provide a summary of the work of the Yale School of the psychology of mental retardation. For those who have valued the frequent critical reviews of Zigler and his colleagues it provides an immensely readable summary which will be valued for its scientific rigour and breadth of interest. Although nearly a third of the references are to the authors' own work, it remains an authoritative text which may be used with value by postgraduate students of all disciplines.

At a time when the concepts of social adaptation and IQ in the identification of people with mental retardation are coming under critical scrutiny, the opening chapters provide a useful account of the issues involved in the debate and argue strongly for the Yale group's insistence on a developmental perspective and aetiological approach to classification. It is persuasively concluded that overzealous avoidance of labelling may be counter-productive in depriving the person with mental handicap of the help he or she needs. For the psychiatrist, the limited discussion of personality and motivational development in a single chapter, while of theoretical interest, will seem too detached from the problems of severe maladaptive behaviour and the difficult issues of their everyday management.

Of more interest are the reviews of specific interventions, particularly in young infants, and the critical account of the search for 'miracle cures' which will prove of particular value in helping to answer the questions of concerned parents.

All through the book there is an emphasis on a humane and caring outlook towards retarded individuals, which tempers the scientific and the critical discussion and search for increased knowledge which provides the main strength of the text.

J. A. CORBETT, *Professor of Mental Handicap, The University of Birmingham*

The Royal College of Psychiatrists. By HENRY R. ROLLIN. London: The Royal College of Psychiatrists. 1987. 15 pp. £2.00.

History becomes alive when it brings insights into present day practice, as admirably demonstrated by this booklet.

A graceful view of Belgrave Square invites us to the Post-Regency mansion that houses the College for a meeting with the author, one scholar Librarian who dedicates his work to another. In tracing the history of the oldest psychiatric professional body in the world, Rollin presents a valuable brief background account of psychiatry in Britain since the 18th century. His history demonstrates that the main professional issues have not changed: each succeeding challenge was met by the foundation of Parliamentary Committee, Council, Divisions, Court of Electors, Journal, Library, etc.

However, two major pieces of unresolved business are exposed by his account. The first, from the last century, left the profession's examination, and thus its standards, in the hands of others. It was rectified by the foundation of the Royal College in 1971. This was what the halting, tortured quest was about. The second remains an issue. As the author points out, from the First World War emerged the psychopathologists. Arising from this, some day an uncomfortable decision will have to be made: should the psychiatrist find fulfillment in a biological approach in his field, or does his true vocation lie in psychopathology, as his title implies – 'healer of the psyche'?

The appeal of this elegant work to Fellow and Member is evident, but the most harassed Inceptor should not fail to put a few minutes aside to enjoy this compelling account of the antecedants and functions of his professional body.

JOHN HOWELLS, *Formerly Director, Institute of Family Psychiatry, Suffolk*

Brain Injury Rehabilitation: A Neurobehavioural Approach. By RODGER Ll. WOOD. Beckenham: Croom Helm. 1987. 196 pp. £17.95.

The author was until recently the senior psychologist at the Brain Injury Rehabilitation Unit at St Andrew's Hospital, Northampton. The main substance of the book is a series of vignettes and single-case studies illustrating the management of aggression and other inappropriate activities with behavioural techniques in a token economy setting. Flanking this core of material is a discussion of the nature and value of a 'neurobehavioural' approach. These chapters are disappointing – particularly the final one, where it is difficult to follow the author's arguments.

It is clear that the unit is managing a highly-selected group of severely brain-damaged individuals. This point is not emphasised by Wood, who fails to extend the discussion to the rehabilitation of the more mildly-afflicted majority. Also, the stressing of behavioural aspects leads to a neglect of other aspects of management such as drugs (except for carbamazepine in aggression).

The book could not be recommended to the generalist or the trainee, as better reviews can be found elsewhere (those of Miller or Levin *et al*, for instance). The clinical sections are probably of value to those involved in related work.

TOM DENING, *Research Fellow, Department of Psychiatry, University of Cambridge*

A HUNDRED YEARS AGO

The Superintendent of the Royal Edinburgh Asylum deals in a very practical manner with many points bearing on insanity in its social relations. Dealing with the question of the nature of the habitation which an asylum ought to provide for its inmates, he says: "It is now generally admitted that for a number of patients we cannot get classification and individualisation enough, if the whole institution is under one roof. We need distinct homes, and houses of different kinds. Many of the patients are capable of living ordinary lives in ordinary houses, *plus* medical supervision and skilled attendance. We need all through the *hospital* and the *home* idea — the hospital and its special arrangements predominating for patients in one state of mind, and the home for others in a different state." The death-rate was 7.7 per cent; and the recovery-rate on admissions was 38.5 per cent.

THE BRITISH JOURNAL OF PSYCHIATRY

November 1987 Vol 151

Published by
The Royal College of Psychiatris

ISSN 0007-1250

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al*, *British Medical Journal*, 7 May 1983, **286**, 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that . . .'

DURKHEIM, E. (1897) Le Suicide. Paris. Translated (1952) as Suicide: A Study in Sociology, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiat c diagnoses. British Journal of Psychiatry, **124**, 352–35

RUTTER, M., TIZARD, J. & WHITMORE, K. (19) Education, Health and Behaviour. London: Longma

SCOTT, P. D. (1974) Definition, classification, progno and treatment. In Pathology and Treatment of Sex Deviation (ed. I. Rosen) Oxford: Oxford Universi Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols a Abbreviations: A Guide for Biological and Medical Edito and Authors* (3rd ed. 1977), £2.00, available from t Publications Office of the Royal Society of Medicine. Ter or abbreviations which might not be understood by t average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separat sheet, with an adequate heading; table and heading should b self-explanatory without reference to the text. The desire position of the table relative to the text should be indicated i the left margin.

Figures should be individual glossy photographs, or othe camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

of
British Columbia

DEPARTMENT OF
PSYCHIATRY

ASSISTANT
PROFESSOR

The Department of Psychiatry has available a tenure track position for an academic psychiatrist with a special interest in research and treatment of schizophrenia.

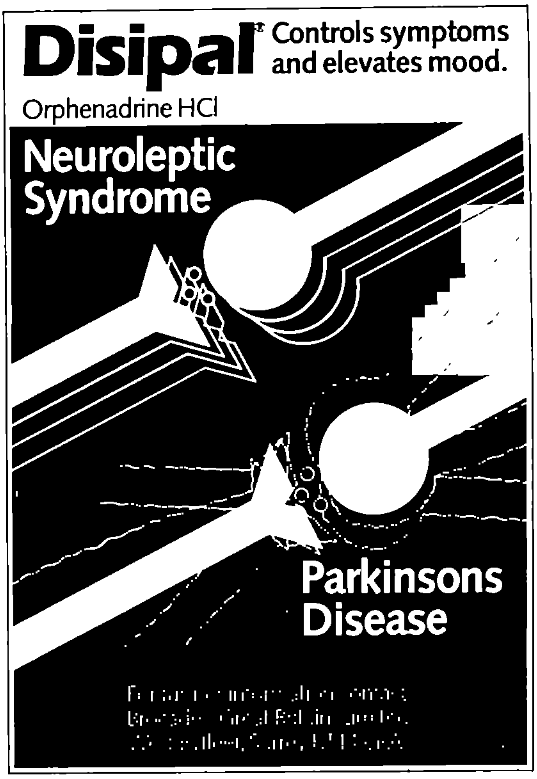
Located in the UBC Health Sciences Centre Hospital, the position includes work as a clinical supervisor of the 20-bed specialized Schizophrenia Ward, and perhaps later on extending to outpatient services; supervision and teaching in both undergraduate and postgraduate programs; and the expectation that the incumbent will engage in clinical research.

The Psychiatric Pavilion of the Health Sciences Centre Hospital includes the distinguished Division of Neurological Sciences where unique opportunities for research exist. The university also has excellent facilities for brain imaging (PET and MRI).

Applicants should have appropriate clinical and teaching experience in Psychiatry and a demonstrable training and aptitude for clinical research. Eligibility for medical licensure in British Columbia is essential. Salary will be commensurate with the requirements of the position.

The appointment is subject to final budgetary approval. Applications, including a curriculum vitae and names of three referees, should be sent to: Dr H. C. Fibiger, Acting Head, Department of Psychiatry, The University of British Columbia, 2211 Wesbrook Mall, Vancouver, B.C., V6R 2R4 Canada.

In accordance with Canadian immigration requirements, preference will be given to Canadian citizens and permanent residents of Canada.



Disipal Controls symptoms and elevates mood.

Orphenadrine HCl

Neuroleptic Syndrome

Parkinsons Disease

FORGE HOUSE
ROMSEY

A new residential nursing home for the treatment of Alcoholism will open on December 1st 1987. Full 24 hour nursing facilities with resident staff and expert counselling.

All enquiries to the Medical Director at Romsey (0794) 388385.

Chief of Service

Alberta Hospital Ponoka, a fully accredited university affiliated adult psychiatric hospital is currently involved in a major redevelopment program which includes the creation of an 80 bed Brain Injury Rehabilitation Unit. An exciting and challenging opportunity is available for a Chief of Service to assist in the planning and development of assessment and admissions requirements and the establishment of clinical procedures.

Once the program is operating the Service Chief (Neuropsychiatrist) will specialize in the provision of direct clinical services including the clinical supervision of a large multi-disciplinary treatment team.

Qualifications will include Canadian Certification (F.R.C.P. (c)) or Graduation from a Category I Medical school with post graduate qualifications, research interest and experience in Neuropsychiatry.

Alberta Hospital Ponoka is a progressive expanding facility located in a rural setting close to the major cities of Calgary and Edmonton and the recreational areas of the Canadian Rocky Mountains.

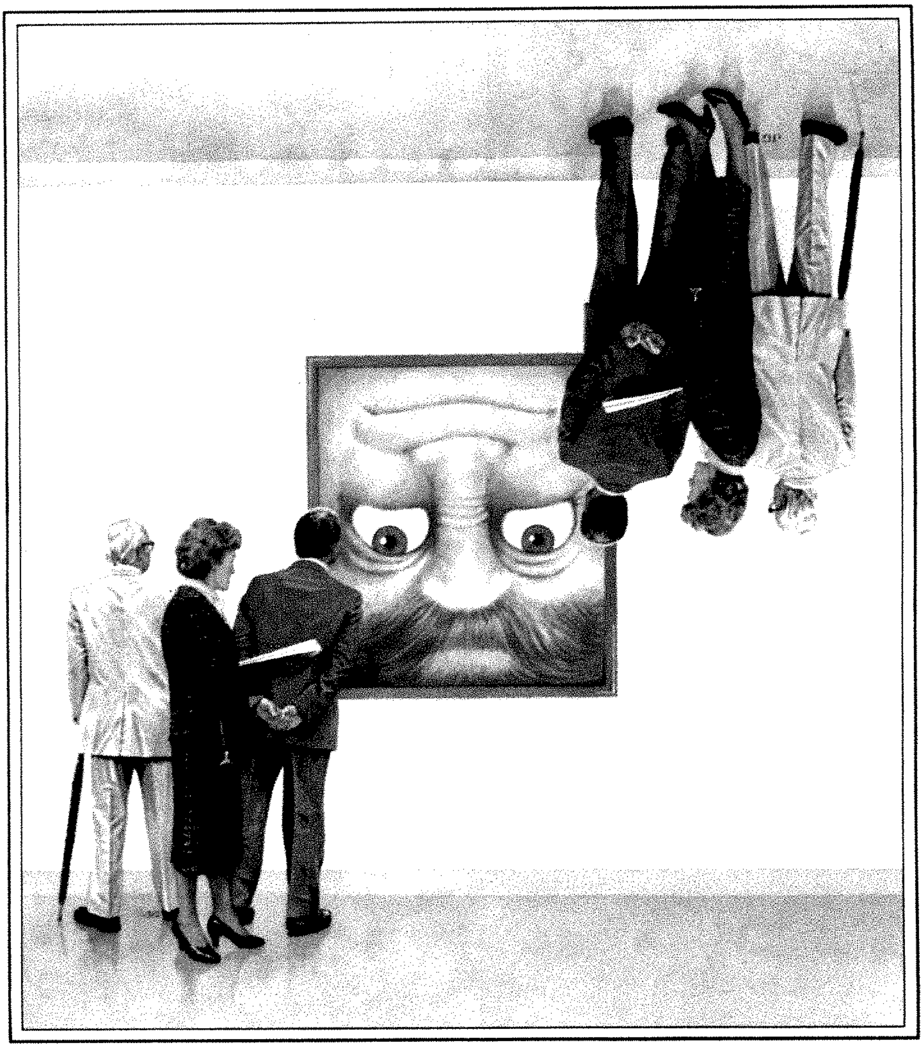
Modecate Abbreviated Prescribing Information. Indications: Treatment of psychotic disorders. **Dosage – Modecate injection 25mg/ml.** Most patients are successfully maintained within the dosage range 12.5mg (0.5ml) every five weeks to 100mg (4ml) every two weeks. For full dosage information see Data Sheet. **Modecate concentrate injection 100mg/ml.** Adult patients found to require larger volumes of Modecate 25mg/ml may be transferred directly to the equivalent dose of Modecate concentrate on the basis that 1ml Modecate concentrate is equivalent to 4ml Modecate. **Contra-indications.** Patients with marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, or severe cardiac insufficiency. **Precautions.** Care should be taken in patients, particularly the elderly, who exhibit marked extrapyramidal reactions to oral phenothiazines. **Side effects.** Mainly extrapyramidal reactions. Drowsiness, lethargy, dryness of the mouth and mild hypotension may occur. **Product Licence No's and Prices. Modecate injection 25mg/ml.** PL 0034/5046. 10 x 1ml ampoule £25.20 **Modecate concentrate injection 100mg/ml.** PL 0034/0189. 10 x 0.5ml ampoule £49.99 5 x 1.0ml ampoule £48.86. Modecate is a Trade Mark of E. R. Squibb & Sons Ltd. Further information available from: Technical Services Department, E. R. Squibb & Sons Ltd., 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. Tel: 01-572 7422.



TRIED AND TRUSTED

19 years ago, E. R. Squibb & Sons helped lead a revolution in the community based treatment of schizophrenia when they introduced the depot neuroleptic concept.
Since then worldwide clinical experience has confirmed the efficacy and safety of Modecate in over 800,000 patients.
Modecate is now regarded by many psychiatrists as the standard depot neuroleptic.

MODECATE®

25 mg/ml 100 mg/ml

FLUPHENAZINE DECANOATE

Modecate is available in two strengths, allowing a wide dosage range with convenient injection volumes.
Most patients can be controlled with an injection at intervals of 3 weeks or more.[1]
Modecate is less expensive than other depot neuroleptics when comparing equipotent doses.

Review Article

AIDS-Related Psychiatric Disorder*

THOMAS W. FENTON

The background to HIV infection, its mode of transmission, and its neurological and psychiatric complications are described. The management of AIDS-related psychiatric disorder and problems encountered among staff involved in the management of patients suffering from AIDS are considered. There is a need for appropriate educational programmes. Although the incidence of AIDS in the UK has been appreciably lower than in many other countries, there are no grounds for complacency; psychiatric disorder associated with HIV infection will be encountered much more frequently in the future. Psychiatric staff are urged to inform and prepare themselves in anticipation of this development.

In the summer of 1981 the Centers for Disease Control (CDC) in Atlanta, USA, first notified the occurrence of illnesses that, in retrospect, were manifestations of the acquired immuno-deficiency syndrome (AIDS) (Centers for Disease Control, 1981*a,b*). It was later recognised, however, that cases of AIDS had been occurring in the USA since at least 1978. Hitherto, illnesses resulting from immunodeficiency had been encountered in patients receiving immuno-suppressant drugs for transplants and malignancies and in infants suffering from congenital immuno-deficiency. It was the reporting, in the USA, of increasing numbers of cases with an immunodeficiency syndrome but having no such cause as this, nor indeed any other apparent cause, that led to the recognition of a new disease entity.

In order to facilitate epidemiological surveillance, the CDC published a formal definition of AIDS in 1982 (Centers for Disease Control, 1982*a,b*). Essentially, this definition advised that the diagnosis of AIDS should be confined to patients having a severe disturbance of cell-mediated immunity resulting in a marked susceptibility to opportunistic infections, such as Pneumocystis pneumonia, or unusual neoplasms, such as Kaposi's sarcoma, but having no known cause of cellular immunodeficiency nor any other cause of reduced resistance reported to be associated with such deficiency.

Two further related syndromes were subsequently described, occurring in the same high-risk groups as does AIDS, but excluded as cases of AIDS by the CDC case definition. The first of these is characterised by persistent generalised lymphadenopathy (PGL), a condition occurring in the absence of symptoms, but subsequently found to be associated with the causal organism by serology. The second syndrome, termed the AIDS-related complex (ARC), is essentially a symptomatic infection with the causal organism in the absence of opportunistic infection or neoplasms. The AIDS-related complex is characterised by persistent generalised lymphadenopathy, severe lethargy and fatigue, significant weight loss, fever and/or nightsweats. Although PGL has appeared to date to have a relatively benign prognosis, approximately one quarter of those with ARC go on to develop opportunistic infection and/or neoplasms, thus qualifying them for the diagnosis of AIDS.

The causal organism was eventually found to be a virus, was first isolated in France in 1983, and named Lymphadenopathy-Associated Virus (LAV). It was subsequently also isolated in the USA and was termed the Human T-Cell Lymphotropic Virus Type III (HTLV-III). The latter nomenclature is also used in the UK. Further isolations were made in France and in the USA and labelled with a variety of acronyms. It has been agreed, however, that all of these viruses, although differently named, are closely related. The International Committee on the Taxonomy of Viruses proposed that the term Human Immunodeficiency Virus (HIV) be used to cover all of these isolates. This proposal has now achieved international acceptance. This paper will employ the term HIV hereafter. The organism is a lentivirus; that is, its replication and the evolution of its morbid pathological effects are very slow. It is also a retrovirus, and therefore transcribes its own genetic code back into the nucleus of the host cell, so modifying it that it continues to manufacture virus until it dies, resulting in a persistent infection. The virus infects the T4-helper lymphocytes which control immune effector mechanisms that attack and destroy invading organisms. T-helper cells become depleted and functionally defective, resulting in reduced stimulation of B-lymphocytes secreting specific antibodies, and reduced stimulation of macrophages and natural killer and killer lymphocytes which attack invading organisms.

---

*Revised version of a paper presented at a meeting of the Midlands Division of the Royal College of Psychiatrists, April 1986.

Thus HIV undermines and compromises the body's defences against alien organisms, rendering it vulnerable to a wide range of infections. Micro-organisms in the environment, and especially those normally found dwelling within various tissues of the body, seize the opportunity created by a compromised immune system to proliferate. Patients are extremely susceptible to opportunistic agents such as viruses, fungi and protozoa. Immunodeficiency also leads to the development of certain types of neoplasm, including, in particular, Kaposi's sarcoma and non-Hodgkin's lymphoma. When HIV infection occurs the host develops antibodies to viral proteins, but these antibodies are unable to neutralise the virus. They do, however, serve as a useful indicator of infection in laboratory tests. The proportion of HIV infections that result in identifiable disease is still uncertain. Several weeks to months after infection occurs, most subjects develop antibodies. Seroconversion may be accompanied by a transient illness resembling glandular fever. For a variable period of time after seroconversion has occurred the virus remains in the body in a latent form. During this latent period infected persons are symptom-free but after an interval varying between several months to several years some go on to develop PGL, ARC or clinical AIDS.

Clinical AIDS appears to be the end stage of infection with HIV. The interval between infection and the development of AIDS is known to vary from one month (Jaffe *et al*, 1985*b*) to at least five years (Jaffe *et al*, 1985*a*). Estimates of the incidence of AIDS among those antibody-positive for HIV have to be based on the limited experience of the past few years. Earlier reports suggested that 9–14% of seropositive cases developed AIDS over a two-year follow-up (Melbye *et al*, 1984; Goedert *et al*, 1984). More recent reports have indicated an incidence of AIDS approximating 25% in seropositive individuals, and an incidence of 34% is reported in one study (Melbye, 1986). It seems likely that the higher rates of AIDS reported in later studies reflect a longer duration of the seropositive state in the subjects under review. While the outlook for those who are seropositive but asymptomatic is clearly uncertain at present, all must be regarded as able to transmit the infection.

Recently evidence has accumulated to indicate that HIV is not only lymphotropic but also neurotropic and can directly infect cells in the central nervous system (CNS) (Ho *et al*, 1985; Levy *et al*, 1985*a*; Shaw *et al*, 1985). A number of fascinating queries arise from this finding. Present evidence is that the occurence of CNS infection in patients with clinical AIDS is common. Is CNS infection in fact invariable? May CNS infection occur in the absence of immunosuppression, so that seropositive patients who escape AIDS or ARC may ultimately succumb to the direct attack by the virus on brain cells? If direct CNS infection can occur in the absence of immunosuppression, could the time-scale of its evolution span a considerably longer period than the evolution of immuno-deficiency? The answers to these questions must abide further experience with the disease and further research. What does seem clear, however, is that over the next decade the neurological consequences of the disease will acquire at least as great a prominence as its immunological consequences, and that the term AIDS – the acquired immunodeficiency syndrome – is no longer an adequate description of the pathological effects of the virus.

It is estimated that at the present time at least 1.5 million people are infected with HIV in the USA. To date nearly 20 000 have developed clinical AIDS (Curran, 1986), of whom about half have died. Although in the early years after 1981, a consistent doubling of cases every six months was reported, the Centers for Disease Control have recently published a report which indicates that, since the outbreak began, the period during which the number of cases of AIDS was doubled lengthened from 5 months in 1982 to 10 months in 1984–1985, and to 11 months in 1985–1986 (Centers for Disease Control, 1986). In other words, within the USA the rate of multiplication in the number of reported cases is declining; a significant factor in this decline may be the widespread adoption of 'safe sex' precautions by homosexuals (Altman, 1986; Golubjatnikov *et al*, 1983). About half a million people are believed to be infected in Europe; it has been conjectured that up to 10 million people may be infected in Central Africa. Since it was defined in 1981, AIDS has been reported throughout the world. In the UK the first case was reported at the end of 1981, and the number of cases reported monthly by the PHLS Communicable Disease Surveillance Centre (CDSC) in Colindale, London, has increased steadily, although so far the incidence of AIDS in the UK has been substantially lower than in many other countries. The CDSC estimates the number of people infected in the UK in 1986 to be of the order of 30 000. At the end of July 1986, 465 cases of clinical AIDS had been reported in the UK, with 234 deaths (CDSC, unpublished).

The virus has been isolated from blood, semen, cervical and vaginal secretions, saliva, tears, breastmilk, cerebrospinal fluid and brain. The principal mode of transmission is sexual intercourse. In the West this has to date been associated with intercourse between male homosexuals in particular, but by no means exclusively (Melbye, 1986). There is strong evidence that in Africa the dominant mode of transmission is heterosexual intercourse (Biggar, 1986; Piot & Mann, 1986). The virus is also transmitted by blood and blood products (Smithies, 1986). Therefore drug users who share needles, syringes and other equipment are at risk, as are haemophiliacs who have been treated with infected pooled factors VIII and IX. Blood transfusion has been a rare source of infection. The virus may be passed from an infected mother to the foetus during pregnancy (Lapointe *et al*, 1985), possibly also at birth and possibly in breastmilk (Ziegler *et al*, 1985). Infection has occurred through transplantation of organs from infected donors (Prompt *et al*, 1985), and through artificial insemination with semen from infected donors (Stewart *et al*, 1985). So far as health care workers are concerned, the risk of infection is probably limited to severe needle-stick injuries (Geddes, 1986). There have been many reports of needle-stick injuries occurring without the injured person becoming seropositive. So far, worldwide, there has been only one recorded case of a health care worker undoubtedly having contracted the virus; this followed a needle-stick injury resulting, at the time of the report, in seroconversion but not clinical AIDS (Lancet, 1984). There is no evidence that HIV is transmitted through casual social contact or by ingestion, droplet-spray or inhalation (Smithies, 1986). A study of 56 adult patients with AIDS or ARC and their 136 non-sexual household contacts over a period of 12 months revealed that no contact acquired infection via sharing of various household items, household facilities and close personal interaction (Saltzman *et al*, 1986).

The fear so universally evoked by AIDS has resulted from several well-established characteristics of the disease. Almost without exception it is a fatal illness; few patients with clinical AIDS live longer than about three years after the diagnosis is made and CDC reports have indicated that 80% die within two years. The diagnosis of AIDS is a catastrophic trauma for its sufferer, because it is known to run a rapidly deteriorating course with no prospect of definitive treatment and a hopeless prognosis. Since it was first identified the disease appears to have spread in a virtually exponential way. There is every reason to believe that those infected, which of course includes the many who are seropositive but symptomless, will remain infectious thereafter, acting as carriers of the virus, and may infect others without being aware that they are doing so. Taking these features into account, in conjunction with the widespread and often distorted publicity that they have received, the great alarm about AIDS which has manifested itself in society is easily understood. Agitation and fear among high risk groups, especially homosexuals, has resulted in a type of behaviour which has been termed 'AIDS panic' and which has led to homosexuals visiting their family practitioner or the local hospital demanding 'AIDS testing' on the first appearance of some skin lesion or of a persistent cough (Deuchar, 1984). AIDS-induced psychogenic states have also been described (Miller *et al*, 1985; O'Brien & Hassanyeh, 1985; Polan *et al*, 1985; Rundell *et al*, 1986; Weber & Goldmeier, 1983), in which individuals, not only those belonging to the high-risk groups, and known in some cases to be seropositive but in others not, have developed a terror of and an intense preoccupation with AIDS, leading to multiple somatic complaints with a conviction of suffering from the disease, together with associated mood disorder and occasionally a conversion reaction. Such patients may become intensely anguished, and preoccupied with thoughts of suicide, and the risk of a suicidal act may be very potent. Indeed, the risk of serious adverse reaction, including suicide, occurring in patients who have been informed that they are seropositive for HIV infection has led to the view being expressed that serological testing should not be carried out unless the patient can be provided with adequate counselling for the results (Miller *et al*, 1986). It has also been suggested that the availability of a widely used screening test creates a new population of patients who will be encountered with AIDS-related psychiatric symptoms resulting from adverse reactions to notification of a positive result (Rundell *et al*, 1986).

The media have had a key role in burdening the public with information which has often been inaccurate and misleading, has fostered the hysteria surrounding AIDS and has fed upon it in turn. Headlines such as "Gay Plague", "Lethal Scourge" and "Killer Epidemic" accompanying sensational accounts of AIDS with overtones of sin and retribution, together with descriptions of children and haemophiliacs as "the innocent victims", have stimulated the fearful imagination and fortified the prejudice of the public. Prejudice and discrimination against AIDS sufferers and their relatives and friends, and also against homosexuals and drug abusers, have been frequent and widespread.

Employers have sacked employees; landlords have evicted tenants suspected of carrying the disease. Dustmen have refused to collect refuse from the houses of known patients. Homosexuals have been refused life insurance; funeral directors have refused to handle the bodies of those who die of the disease. Prison inmates have gone on hunger strike, demanding that all homosexuals and intravenous drug abusers be banned from the kitchen; prison guards have asked for protective masks, and have demanded that all prisoners with AIDS be isolated. Parents have prevented their children from having any contact with a child known to suffer from AIDS, have kept them away from school, and have even kept them away from school where the relatives of AIDS patients attended. People have withdrawn their custom from restaurants, shops and hairdressers known to be frequented by those with AIDS. Hospital unions have tried to exclude AIDS sufferers from medical care; health care workers have been reluctant to care for them, change their beds, bathe them, take their meals or draw blood from them.

The overwhelming psychological trauma and sense of threat experienced by those who have contracted the disease is undoubtedly intensified by the frightening and often misleading media comment and by the irrational fears and negative discriminatory responses of the public. Taking account of the psychological stresses occasioned by awareness of being infected, and the interpersonal, intrafamilial, social and occupational consequences of the disease, together with the high incidence of neurological complications, that psychiatric disorder has proved to be a common accompaniment of AIDS is matter for no surprise. The American experience appears to have been that psychiatric consultations are most frequently requested to evaluate depressive symptoms, suicidal risk, and disturbed behaviour related to CNS impairment associated with dementia or delirium (Dilley *et al*, 1985; Holland & Tross, 1985). Mood disorder is a very common psychiatric complication (Rundell *et al*, 1986), and it is said that this has been most commonly diagnosed as an adjustment reaction with depressed or anxious mood (Holland & Tross, 1985). Psychotic depression is quite frequently encountered, although often, as might be anticipated, with a previous history of affective illness. Less commonly a neurotic depression is diagnosed. A mood of sadness, hopelessness and helplessness is characteristic, often associated with guilt, low self-esteem and feelings of worthlessness. Social withdrawal and isolation and also anticipatory grief are common accompaniments. Suicidal ideas may become prominent as the disease progresses, especially in those who have seen friends die from AIDS.

Obsessive–compulsive disorders are also encountered in the context of AIDS. Obsessional thoughts and behaviours may arise in the setting of depressed mood, but also occur independently. Such symptoms may arise not only in those suffering from clinical AIDS, but also in patients with ARC or those who are seropositive but otherwise well. Obsessional behaviour may take the form of repetitive checking of the body for skin rashes or other blemishes, a ritual which may occupy several hours every day (Miller, 1986). Obsessional thoughts may include unpleasant ruminations about death and dying, or a constant endeavour to recollect the past history of sexual practices and sexual partners, seeking to identify how and from whom the infection was contracted. They may also be concerned with a repetitive scanning of past events centred on fears that the patient may have accidentally transmitted infection to family or friends (Green, 1986).

There has been comment upon the common occurrence of certain psychological themes in patients showing psychiatric disorder, and which seem particularly relevant to the patient with mood disorder (Dilley *et al*, 1985; Holland & Tross, 1985; Nichols, 1985). Uncertainty surrounding the aetiology, course and treatment of the disease, and about modifications in life-style which may be required results in anger which may be directed towards caregivers. Social isolation is frequent, resulting from inability to follow occupation, diminution of sexual contacts and social withdrawal. Patients' fears that others seek to avoid them may be intensified by isolation precautions and by the failure of family and friends to support and visit them during their stay in hospital. For some patients the diagnosis of AIDS precipitates conflict about their sexual orientation. This may lead to the notion of illness being a retribution for promiscuity, and guilt about their sexual orientation. Such conflicts and related guilt may be accentuated as a result of shunning by others and may generate feelings of being unclean or dirty. Reactions of a kind experienced by those facing a life-threatening illness may also be shown. These include feelings of numbness and anger, fears of disability and of loss of body control, of pain and death. Above all there is a sense of loss: loss of physical stamina and health, of capacity for employment and income and often of relationships with others. A sense of time running out and of unfinished business in relation to interpersonal and family problems, and the possibilities of solving or easing these inevitably intensifies the depressed mood.

Neurological complications are a common feature of the disease (Levy *et al*, 1985*b*; Perry & Jacobsen, 1986; Snider *et al*, 1983). The most common forms of cerebral pathology related to

AIDS are encephalopathy, meningitis and neoplastic disease. At autopsy, evidence of encephalopathy is the most common CNS finding. This may be associated with post-mortem findings of various opportunistic infections such as the protozoal infection toxoplasmosis, producing a necrotic intracerebral mass associated with cyst formation; cerebral abscesses due to herpes-group viruses; and a progressive multifocal leukoencephalopathy due to papovavirus infection. Much the most common form of encephalopathy, however, and indeed the most common type of cerebral pathology affecting patients with AIDS, is that form which has been entitled 'subacute encephalitis' in the American literature (Levy *et al*, 1985*b*; Perry & Jacobsen, 1986; Snider *et al*, 1983). This encephalopathy is characterised by focal necrosis in grey and white matter, the formation of multiple microglial nodules in grey matter and to a lesser extent in white matter, gliosis of the cerberal cortex and subcortical nuclei associated with neuronal loss, microfocal demyelination and cerebral atrophy. This condition is now believed to be due to primary infection by HIV (Ho *et al*, 1985; Shaw *et al*, 1985). Meningitis is most often due to an opportunistic fungal infection such as cryptococcus. Aseptic meningitis has also been reported and is suspected to be due to one of the viruses of the herpes group. Although primary CNS lymphoma is the most common neoplasm encountered at autopsy, systemic lymphomas with CNS involvement have also been reported, including large-cell lymphoma, immunoblastic sarcoma, plasmacytoma and tumours resembling Burkitt's lymphoma. These systemic lymphomas frequently invade the meninges. Occasionally, cerebral and cerebellar metastases of Kaposi's sarcoma have been encountered (Levy *et al*, 1985*b*). Cerebro-vascular complications also occur, including cerebral infarction, intracerebral haemorrhage and subarachnoid haemorrhage, all presumably arising as a consequence of AIDS. Cranial nerve dysfunction and peripheral polyneuropathy may be additional manifestations of nervous system pathology associated with AIDS (Levy *et al*, 1985*b*; Snider *et al*, 1983).

Although dementia may result from cerebral opportunistic infections, it now seems certain that it is most commonly associated with primary HIV infection of the brain. This latter condition has been labelled the AIDS dementia complex (ADC). This complex is said to be the most common neurological complication of AIDS and to feature in the clinical course in the majority of AIDS patients, indeed on occasion being the predominant or even sole manifestation of infection by the virus (Price & Navia, 1986). ADC manifests itself as a combination of cognitive, motor and behavioural disturbances occurring with variable emphasis, cognitive impairment predominating in most patients, but motor or behavioural dysfunction being more prominent in others. Initial complaints of poor concentration and mental slowing, impairment of recent memory, lack of co-ordination and unsteady gait, and social withdrawal and apathy may be overlooked or regarded as features of depressive disorder. Motor disturbance may present early in the clinical course, with tremor, slowness of rapid alternating movements, and ataxia (Navia & Price, 1986). Over several months, but sometimes within the course of a few weeks, cognitive disturbance progresses remorselessly in the majority to a picture of profound global dementia associated with mutism, incontinence and eventual coma, death usually resulting from intercurrent infection. An EEG recording is the most useful investigation, eventually showing non-focal diffuse slowing, but sometimes revealing little abnormality in the early stages. Cerebrospinal fluid examination may reveal no abnormality or only a slight elevation of protein and slight cell increase. Computerised tomography reveals cortical atrophy in about two-thirds of cases.

A number of case reports have indicated the difficulty of diagnosing AIDS-related organic syndromes, especially in the early stages of the disease (Kermani *et al*, 1984; Nurnberg *et al*, 1984; Perry & Jacobsen, 1986; Thomas *et al*, 1985). Mood disturbance is common among sufferers from AIDS and this may mask the onset of dementia for some time, as may the symptoms of lethargy, apathy and withdrawal which are so frequently experienced by AIDS patients. There is the additional difficulty that dementia occurring in AIDS patients is quite frequently punctuated by episodes characterised by pronounced psychotic features which may mimic functional disorder such as schizophreniform psychosis (Perry & Jacobsen, 1986), acute paranoid psychosis (Perry & Jacobsen, 1986), depressive psychosis (Hoffman, 1984; Nurnberg *et al*, 1984; Perry & Jacobsen, 1986; Rundell *et al*, 1986), and hypomania (Kermani *et al*, 1985; Gabel *et al*, 1986; Perry & Jacobsen, 1986). Symptoms may include delusional thinking, hallucinations, suspiciousness, grandiosity, rambling and repetitive speech, and blunted affect. Mood disorder or psychotic episodes of this kind appear quite commonly to precede obvious cognitive deficit, sometimes by periods of several months. Two important considerations arise in relation to these findings. Firstly, it will be important to be alert to the possibility of AIDS-related psychiatric disorder when a major functional psychosis occurs in the context of a patient belonging to one of the known high-risk groups for AIDS. Secondly, when an apparent functional psychosis occurs in a known AIDS patient, the possibility will need to be borne in mind that the disorder reflects serious organic brain dysfunction.

There is an interesting parallel with another type of encephalitis which is also believed due to virus infection. The condition is generally referred to as subacute sclerosing panencephalitis, a collective term for several conditions which were previously identified by separate names, including Dawson's subacute inclusion body encephalitis and van Bogaert's subacute sclerosing leukoencephalitis (Lishman, 1978). In recent years evidence has accumulated to suggest that a virus similar to or identical with the measles virus is the cause of these conditions. The illness commonly presents with features of dementia but in some cases the presentation may resemble a functional psychiatric illness, and this has led to initial diagnosis of depression, schizophrenia or hysteria. The condition appears to be reminiscent of the syndrome associated with organic mental disorder related to AIDS infection.

It is not known whether CNS involvement is an invariable accompaniment of clinical AIDS. Certainly the occurrence of cognitive dysfunction is common (Price & Navia, 1986), and in one study was reported to have developed in more than 50% of patients (Holland & Tross, 1985). As well as dementia, the other type of organic mental disturbance quite frequently seen in association with clinical AIDS is a delirious reaction (Holland & Tross, 1985; Miller, 1986). This may occur in the setting of established dementia, or result from opportunistic infection of the respiratory tract, alimentary tract and central nervous system, or from malignancies in the brain.

When undertaking assessment of an AIDS patient presenting with psychiatric disorder, it will obviously be important at an early stage to determine, if possible, whether the condition has an organic basis. This will be a logical first step in the light of the known frequency of neurological complications such as encephalopathy due to HIV infection, progressive multifocal leukoencephalopathy and primary or secondary CNS neoplasms. When in-patient psychiatric care is indicated, the question arises as to what facility is best suited to the patient's needs. Those known to have AIDS or ARC and who are presenting with an acute psychotic state need to be investigated first of all in a medical ward to identify any possible organic lesion and to determine whether this is treatable or not. Once this has been done it will be appropriate for them to be transferred to a psychiatric unit, although they will need regular medical review by a physician having special experience in AIDS. Chronic psychotic patients who develop AIDS or ARC and who require in-patient care, and also AIDS sufferers who develop an intercurrent psychosis such as the depressive or manic phase of an existing manic–depressive illness, will be best managed in a psychiatric unit.

Patients will not need to be nursed in isolation unless certain problems arise which create exceptional risk of infection being transmitted (Geddes, 1986). The patients concerned will include those who are bleeding profusely, suffering from diarrhoea, or suffering from intercurrent infection with an infectious disease such as tuberculosis or salmonella; also patients who are acutely psychotic with disturbed behaviour likely to lead to violence by the patient or being offered to the patient by others. There are of course compassionate grounds for nursing in isolation those patients requiring terminal care. The risks which may be encountered in relation to managing AIDS patients in a psychiatric unit will include contamination risk from blood spilled in a violent incident or from self-injury, that risk being greatest where the person contaminated has also been injured or if contaminated blood contacts an already existing cut or graze; needle-stick injuries sustained by nursing staff when giving injections, or by doctors and pathology staff when carrying out venipuncture; and the possibility that the patient may infect others by promiscuous sexual behaviour. Staff caring for AIDS patients should exercise precautions aimed at reducing exposure to blood and body fluids and reducing transmission of opportunistic organisms (Geddes, 1986; Levy *et al*, 1985*b*). These will include the wearing of gloves and a plastic apron when attending to the patient, and when handling blood samples, tissue specimens, secretions or excretions, and items and surfaces which have been soiled by any of these. Sodium hypochlorite solution (10 000 ppm available chlorine) should be employed to disinfect after blood spillage and to disinfect work surfaces after use. Care must be taken to avoid accidental wounding with potentially contaminated material; needles should not be re-inserted into their original sheaths, but disposed of promptly in puncture-resistant containers. Contact of an open lesion with material from AIDS patients must be avoided.

When devising a strategy for the management of patients with AIDS-related psychiatric disorder, it will be important to bear in mind that characteristically AIDS is a chronic illness with acute exacerbations, although ultimately fatal. In the light of this longer perspective, counselling and a supportive type of psychotherapy will often be a very important aspect of case management, and a number of issues will require attention (Holland & Tross, 1985; Green, 1986; Miller, 1986; Perry & Jacobsen, 1986). It will be important to help the patient to understand current information about the disease, its cause, the modes of transmission, and the treatment that is available. Advice should be given on such precautions as may be necessary to prevent possible transmission of infection to partners, friends, household members, and family. Advice with regard to the adoption of 'safe sex' practices with partners will be of crucial importance. Such advice should encompass reduction in the number of sexual partners; the use of a condom and if need be extra lubrication for heterosexual intercourse; the total avoidance of anal sex, or the use of a condom and extra lubrication if anal sex is not avoided; avoidance of the transfer of body fluids, including 'deep kissing'; discussion of 'safe sex' guidelines with existing and prospective partners; the need for regular venereological screening; the desirability of keeping to body rubbing and mutual masturbation (Green, 1986). Even though it is highly unlikely that the advice will be followed, intravenous drug abusers should be firmly counselled that the only truly safe course of action for them is to renounce all forms of drug abuse. It will be essential to strongly advise that the patient should refrain from sharing drugs and equipment, and use only new needles, and also to advise about the sterilisation of equipment for injection. Interesting schemes are now being operated in Rotterdam and Amsterdam, Holland, whereby through the aegis of a private trust or the city council, drug-abusing prostitutes are offered the facility of free needle exchange on a clean-for-dirty basis (Beasley, unpublished). Such schemes have much to commend them, and it will be interesting to learn whether they will reduce the risk of seroconversion among the drug-abusing subculture.

Patients should be allowed to ventilate their anger about the negative reaction of others and public prejudice about the illness, and be helped to avoid acting out their feelings with self-destructive behaviour. They are likely to benefit from encouragement to discuss their feelings about the illness, and their fears for the future. Concern on the part of the staff for distressing symptoms and a compassionate understanding of emotional problems are obvious supportive measures. It will be helpful to offer realistic reassurance in the context of the current clinical situation, but the patient's awareness of a fatal outcome to his illness needs to be acknowledged, if expressed. This will allow appropriate attention to be given in counselling to practical matters such as arranging financial affairs, preparing a will, and perhaps seeking a reconciliation with family and friends. Patients may need and should be afforded an opportunity to discuss concerns about death, arrangements for terminal care, and a wish to seek the consolations of their religion. Discussions will also be needed with members of the family, the patient's friends and also carers in the community to provide sustained and structured social support. Referral to local self-help AIDS crisis organisations, where these exist, may prove very useful also (Nichols, 1983; Deuchar, 1984; Altman, 1986; Perry & Jacobsen, 1986). In view of the social implications of AIDS, early referral to a social worker is likely to be required for the planning of physical and financial assistance and referral to such self-help organisations.

Since mood disorder and severe stress may themselves exert immuno-suppressive effects (Stein *et al*, 1976; Bartrop *et al*, 1977; Cappel *et al*, 1978; Schliefer *et al*, 1983; Schliefer *et al*, 1984), the need for measures to alleviate anxiety and depressed mood becomes so much the stronger. With the great majority of patients, the management of anxiety is likely to play an important part in overall management (Green, 1986; Miller, 1986). Uncertainty about the disease and its treatment, preoccupation about its potential for a rapidly declining course to death, and alarm about any new physical symptoms are all potent causes for distress. The somatic accompaniments of anxiety may themselves be a source of further distress as they may be misinterpreted as additional evidence of a deterioration in physical health. Patients will need to be given an opportunity to air their anxieties about the illness, its treatment and its personal and social consequences. The nature of anxiety symptoms will require careful explanation. Relaxation training and other anxiety-management techniques will be useful adjuncts to management.

Since depressed mood is so common among AIDS patients, psychological techniques for its relief will be of importance also (Green, 1986; Miller, 1986). These are likely to involve encouraging an increase in social activity in order that benefit may be obtained from some renewal of physical stamina and the resumption of enjoyable activities and leisure pursuits. Where resumption of work is feasible, this should be encouraged as an activity tending to offer distraction from negative depressing preoccupations. Specific cognitive techniques may need to be employed to reduce negative thinking and to counter automatic assumptions that all efforts to improve the quality of life are pointless.

It will be important to be alert to the possibilities of suicide risk since many of the factors known to be associated with increased risk of suicide are operative with these patients (Holland & Tross, 1985; Green, 1986; Miller, 1986). Thus they have experienced recent trauma, including the diagnosis and consequences of the illness, many are very depressed, they may have suffered the loss of a loved one from AIDS, they may be socially isolated, their physical health is deteriorating, and they may have experienced recent financial hardship.

For very obvious reasons, patients with ARC are also likely to experience high degrees of psychological distress (Holland & Tross, 1985). The implications of the diagnosis and the uncertainty of outcome commonly dominate thinking, and indeed these patients may show even higher levels of distress than those with clinical AIDS. Counselling in regard to risk reduction by altering sexual behaviour and by taking appropriate precautions with regard to intravenous drug abuse will be of equal importance with these patients in order to limit progression of the disease and protect others. Patients with ARC may also require supportive psychotherapy informed by largely the same principles as obtain in the case of patients suffering from clinical AIDS.

Psychotropic drug therapy for AIDS patients with symptoms of anxiety, depression and psychosis is similar to that for patients with other affective and organic mental disorder. Anxiolytic medication and the use of antidepressants, particularly tricyclic drugs, may afford useful symptomatic relief, but side-effects such as postural hypotension, sedation and confusion may be more troublesome with these patients. Also, a high sensitivity to the extrapyramidal side-effects of phenothiazines and butyrophenones may be encountered, and here thioridazine may prove to be more useful than other major tranquillisers.

Unless staff are adequately prepared for the task, the management of patients with AIDS-related psychiatric disorder is likely to create a high level of anxiety, tension, and uncertainty among the staff themselves, with adverse consequences for their patients (Holland & Tross, 1985; Polan *et al*, 1985; Thompson *et al*, 1986); indeed, it has been remarked that even with optimal management of patients, psychiatric staff involved in their care are likely to experience persistent anxiety and uncertainty. Problems described include feelings of repugnance towards patients because of their illness or life-style, reluctance to nurse and avoidance of patients, a readiness to allow withdrawn patients to persist in their self-isolation, constant discussion about the risk of exposure to AIDS, fear of having developed AIDS progressing sometimes to AIDS panic (Polan *et al*, 1985). A survey of employees of a large urban hospital in America revealed that half of those responding believed that AIDS can be spread through casual social contact; 15% believed that AIDS is more common among health care workers than other groups; about half recognised that they spent less time with AIDS patients and about a third admitted that they actively avoided involvement with AIDS patients; a quarter of the workers expressed extreme anxiety about dealing with AIDS patients. Accurate knowledge about AIDS and its transmission was correlated to a high degree of significance with low anxiety as expressed by a self-rating anxiety scale, a willingness to work with AIDS patients and appropriate professional attitudes towards them (Gordin *et al*, 1986).

It seems clear then that the fears of health care workers will diminish appreciably if educational programmes and opportunities to ventilate those fears are offered to them. Educational programmes should afford opportunities to focus on certain key issues relating to staff attitudes and feelings. In this context there will be a need to encourage care workers to be aware of their own negative attitudes towards patients with AIDS, prejudice about alien life-styles and fears of contagion. They should be helped to acquire enough knowledge about bisexuality and homosexuality to understand the issues as they relate to transmission of the AIDS virus, and helped to be able to feel comfortable when discussing sexual matters with patients. The importance of being able to offer information and advice about factors contributing to AIDS infection will need to be stressed, with strong emphasis on the avoidance of moral posturing (Dilley *et al*, 1985; Holland & Tross, 1985).

Up to the present time the lack of information and preparation among psychiatric staff has been of little consequence in the UK because of the low incidence of the disease so far. It cannot be too strongly stressed, however, that there are no grounds for complacency on this score. When AIDS was first identified in the USA it seemed that it was confined to homosexual men, and so it was characterised by the media as a "Gay Plague". Soon after, it became apparent that intravenous drug abusers were contracting the disease because of their practice of sharing needles. Later it was observed that in Africa the ratio of men to women with AIDS is approximately one to one, that there is compelling evidence of heterosexual transmission, and indeed that in Africa this may be the dominant mode. There is now a growing incidence of heterosexual transmission in the West, with bisexual men, prostitutes and the partners of intravenous drug abusers acting as a 'cross-over group' in spreading the disease to the population at large. It is extremely likely that the virus is being spread rapidly by the re-use of unsterilised hypodermic syringes and contaminated needles for injections of vaccines and medicines, a practice which is widespread in Third World countries (Seale, 1986). Given these facts it has been very complacent to perpetuate the illusion that the disease will remain largely confined to the homosexual and drug-using subcultures.

AIDS is characterised by a very lengthy latent period and by lifelong infection. This creates the possibility of an enormous reservoir of individuals who, being asymptomatic and therefore unaware that they are infected, may infect others without being aware that they are doing so. The spread of HIV and the occurrence of AIDS are both increasing at an alarming rate, and it is obvious that so far we have only seen the tip of the iceberg, as it were. In some parts of Africa there is already evidence that up to 25% of the population are infected. The possibility that a significant proportion of the American population may become infected over the next decade, with a similar trend in Europe a few years delayed, presumably cannot be totally discounted.

There are indications that HIV infection of the central nervous system can occur before or in the absence of immuno-deficiency (Ho *et al*, 1985; Price & Navia, 1986). HIV shares with the measles virus and with the visna virus, an organism responsible for slowly progressive degenerative neurological disease of sheep, the property of combined lymphotropism and neurotropism. Although most of the experimental evidence relates to visna and measles, it has been suggested (Black, 1985) that probably all of these infections may persist in the central nervous system, even in the absence of clinical manifestations, for many years. If this is so, and since it appears that primary HIV infection of the brain can occur without immunosuppression, then pre-senile dementia from this cause may ultimately become a commonly encountered condition. The implication here is that if the immune system is not attacked by the virus, there may be a considerable likelihood that in the fullness of time, possibly several years later, encephalopathy and dementia may result from primary HIV brain infection. This is speculation, however; what we may confidently expect is that we will encounter AIDS-related psychiatric disorder with ever increasing frequency in the years to come. Unless an effective vaccine and/or drug therapy is discovered soon, and this seems unlikely, there is good reason to suppose that by the mid-1990s psychiatry will have become a 'front-line' speciality in the management of AIDS victims.

It is essential that mental health care workers prepare and inform themselves about the nature and scope of the problem and its attendant socio-cultural aspects. Only if they do so will they be able to manage their patients effectively and with dignity and compassion. It is hoped that this paper will be a contribution towards that end.

Schizophrenia therapy: the importance of balance

Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets this critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.[1]

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,[2-5] and because injections need only be given every four weeks, patients hardly know they are being treated.

Piportil
DEPOT PIPOTHIAZINE PALMITATE

Piportil Depot Prescribing Information
Dosage: *(Adults)* Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg (1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, severe cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, depression, blurred vision, asthenia, impotence, dry mouth, hyperhydrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08½ ampoules (PL0012/0117). **References:** 1. Presentation: Prothiaden is Dothiepin Hydrochloride B.P. an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily. based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 × 75mg £4.00 as at 1st Oct. 1987. **Product Licence Numbers:** PL0014/5941. PL0014/0209. The Boots Company PLC. Nottingham. England. Further information available on request. ETH 1174/9/87

A common cry for help. Perhaps triggered by one or more factors. But, all too often, diagnosis of the root cause of their problem is clouded by anxiety or somatic symptoms masking the underlying condition. You can trust Prothiaden to brighten up their lives.

Millions of prescriptions make Prothiaden the UK's most widely prescribed antidepressant. After 18 years of clinical experience, Prothiaden's safety is known. Its performance unsurpassed.

So, paint a brighter picture for your elderly patients who find they can't cope – with a prescription for Prothiaden.

The Grammar of Psychotherapy
A Descriptive Account

JOHN P. COBB and STUART LIEBERMAN

The Grammar of Psychotherapy is a method of teaching both communication skills and the elements of psychotherapy. Supervised training is supplemented by self-monitored tasks. The course is economical in terms of tutors' time, and is particularly suitable for trainees in general psychiatry.

Psychiatrists spend much of their time talking with their patients. Even when not engaged in formal psychotherapy, the abilities to converse effectively and to understand their patients in psychological terms are essential psychiatric 'tools of the trade'.

Whether or not basic psychotherapeutic skills can be learned through technical training is keenly debated. The traditional view is that effective psychotherapy owes as much to non-specific factors as to technical expertise acquired through specific training (Frank, 1978). Research over the past 30 years has increasingly challenged this negative view. Rogers (1951) was the first to use audiotaped recordings of therapist–patient sessions as a means of both studying what went on in the sessions and training students. His colleagues (Truax & Carkhuff, 1967) identified specific effective therapist behaviours that could be acquired through relatively short training programmes. This approach was further refined and developed by a team of workers in Massachusetts, whose approach was labelled 'micro-counselling' (Ivey & Simek-Downing, 1980). A micro-counselling programme is structured to focus on teaching 'key' components of therapist behaviour. Control studies showed that specific skills such as attentiveness, accurate reflection, and summarisation of feelings occurring in the session can be taught by a five-hour structured training programme (Ivey & Simek-Downing, 1980). For example, after training, therapists interrupted less, spoke less and increased their response delay.

Similar work has also shown that specific interactional skills can be taught in both behavioural psychotherapy (Loeber & Weisman, 1975) and cognitive therapy (Beck *et al*, 1979). Several components are found in most training programmes. The training is introduced by a descriptive lecture, which is illustrated by a live or videotaped demonstration. Skills are then practised through role-play followed by feedback and discussion. Finally, supervision of patient interviews recorded on audio or video tapes provides a basis for discussion involving both supervisor and peer group.

This type of research has been criticised. Much of the early work done by the Rogerian school focused on therapist behaviour out of context of the interaction with the patient. More recent work has stressed the importance of looking at therapist behaviour from the patients' perspective, as well as from the view of independent judges. Much of the research has been done on neophyte therapist professionals or non-professional mental health trainees, such as undergraduates, parents, or teachers.

Several authors in the USA (Goin & Kline, 1974; Reiss, 1975; Friedmann *et al*, 1978) have discussed psychotherapy training for junior psychiatrists. Some favour traditional supervision; others found new techniques, such as videotape feedback, to be effective alternatives. In the UK, Cox *et al* (1981*a,b*) showed that psychiatric interviewing style could be studied effectively and conclusions drawn about the effects of various styles. Recently Goldberg *et al* (1984) and Maguire *et al* (1984) evaluated a teaching package which aimed to teach 'The Conversational Model' (Hobson, 1977) of psychotherapy to junior psychiatrists. This package included a booklet, two self-teaching videotapes, eight weekly seminars led by a trainer who supervised role-play, and videotape feedback of trainees' interviews. Basic psychotherapy skills can be taught to junior doctors using such a training package. Similar results have been found in teaching interviewing skills to medical students (Maguire *et al*, 1978).

Postgraduate psychotherapy training for psychiatrists may be viewed as a 'soft' area as far as data is concerned and thereby does not lend itself easily to scientific studies. Above all is the difficulty of determining the meaning of 'success' as far as training is concerned. Therapists' behaviour which is approved of by trainers may not necessarily be that which is effective in producing change with patients.

In any case, such change is difficult to measure. Because of the time-consuming nature of measurement, the number of trainee studies is likely to be small (Matarazzo, 1978). The population of patients varies from centre to centre, as does the general attitude towards psychotherapy as a method of treatment. Psychotherapeutic methods themselves vary widely, and the personality of teachers may be highly influential with trainees, but is difficult to quantify. The time available for training is variable, as is the commitment given by each junior doctor. Despite these objections, surveys of general consultant psychiatrists indicate that they recognise the importance of training in psychotherapeutic skills (Lieberman *et al*, 1978; Hafner *et al*, 1977; Scorer, 1985).

Course

Aims and structure

Faced with the task of teaching psychotherapeutic skills to over 100 psychiatric trainees scattered throughout the South West Thames Region, we have independently developed a systematic course whose content is derived from work done by Maguire *et al* (1978), Heron (1975), and Ivey & Simek-Downing (1980), and whose philosophy follows that of Sullivan, Freud and Rogers. The aims are to teach

(a) simple interview skills such as the collection of objective information, the communication of clear instructions and ways of structuring the interview
(b) complex psychological and interactional skills such as the ability to be sensitive to important psychological and emotional issues, the capacity to construct possible alternative hypotheses to understand the patient's problems in psychological terms; the ability to circumvent or modify rigid attitudes; and an awareness of the importance of the therapeutic relationship and the various factors which can modify this.

'Grammar' may be defined as the art and science concerned with a language's inflections or other means of showing relations between words as used in speech or writing, its phonetic system, and the established rules for using these. We use the word 'grammar' as a metaphor because it sums up our belief that we are teaching the study of components of that process of communication which is the basis of a working relationship between therapist and patient.

For teaching purposes we looked at three different levels of interaction. The most superficial of these focuses on the basic skills used by the therapist. Deficiencies in these basic skills may for example be demonstrated by the trainee who finds difficulty in getting patients to talk at the beginning of the interview and equal difficulty in stopping them talking at the end. The second level looks at a wider issue stressed in the writings of Ivey & Simek-Downing (1980) and Heron (1975). This is concerned with the therapist's intent in the interview and is one of the key factors which distinguishes a professional interview from an ordinary conversation. A common example of the way that this can go wrong is when a trainee who intends to take a history starts the interview with a series of confronting statements, and is then surprised that the patient clams up.

The final level of interaction looks at the interview as a whole and asks the questions "What was the therapist's understanding of the patient's problem?" and "What were the factors affecting the therapeutic relationship?".

General description

The Grammar of Psychotherapy course was planned to include 13½ hours of teaching time, starting with six consecutive weekly seminars. Three 1½ hour seminars were devoted to theoretical teaching using both lecture and role-play. Three written handouts were distributed and a multiple choice question (MCQ) test on the content was administered following the last theoretical seminar.

The theoretical seminars were followed by three 1½ hour audiotape supervision sessions in which small groups of students (3–6) presented their audiotapes for scrutiny by peers and one of the trainers.

Three follow-up supervision sessions took place six months later. These were consolidation sessions of a similar nature to the last three feedback sessions.

Specific components

The specific components included the interactograms, the role-play and the audiotape supervision sessions.

Reading material was prepared from various sources and presented as handouts. The first handout provided some theoretical information about the developmental aspects of verbal and non-verbal communication and interpersonal relationships. The second handout was about verbal and vocal communication skills. The third handout went into a number of factors which determine the way in which therapeutic relationships develop. Students were given an MCQ test which was based on this material.

Interactograms

The interactograms served to engage the students by involving them in a series of self-monitoring tasks. Attention was focused by those tasks on the students' current range of interactional skills, and psychological understanding. Trainees were encouraged to discuss their own interactograms and to pick out the aspects of their interviewing styles with which they were satisfied and also those things they would like to change. They were invited to show their interactograms to the rest of the group to ask for comment. Interactogram 1 deals with the simple basic skills of interview technique. Interactogram 2 deals with the intention of the doctor while doing his or her interview with the patient. Interactogram 3 deals with the doctor's mental set and the issues of transference and countertransference. These instruments are described in greater detail in the accompanying paper (Lieberman & Cobb, 1987).

Role-play

Role-play was used extensively in the teaching seminars, and during the feedback sessions if students had difficulty in recording live patient interviews. Role-play requires the student to attempt to see the world from the patient's viewpoint, as well as giving an opportunity to rehearse new skills. Earlier in the first training session one trainer took the role of a patient and the other the role of the doctor. The patient chosen was determined through discussion with the students about their own patients. The demonstration introduced the trainees to role-play as a technique and generated audiotaped material, which was then analysed with the group using the first interactogram.

Later the students were asked to role-play patient and doctor in exercises designated to restrict the doctor's repertoire. These 'restriction exercises' were based on previous knowledge of students' patterns of interaction. For example, if the use of silence was rare, students were asked to practise pausing for at least three seconds between the patient's response and the next therapist intervention. If students used a 'cross-examination' style consisting of an endless series of questions, the rules of the restriction exercise would confine the therapist to statements only.

Later in the course, restriction exercises gave the opportunity to examine problems associated with those intents that students found difficult. In particular, students wanted help with confrontation and catharsis. For example, as an exercise on confrontation, students are divided into groups of three with a protagonist, agonist, and observer. A 'doctor' is asked to confront the 'patient' in a clinical situation. The 'observer' marks the interactogram, including which particular microskills were used. The object of the exercise is to encourage the patient to look at his behaviour without damaging the doctor–patient relationship. After five minutes the 'doctor' discusses what he did, noting both good points and those points he would like to change. The 'observer' gives an account of what he sees. The 'patient' describes his feelings and his reaction to the therapist. He discusses whether he could see what the doctor was driving at and whether change was likely. This exercise is then repeated, with everyone swapping roles until all participants have had a chance to be 'doctor', 'patient', and 'observer'.

Seminar 1

The first seminar started with a role-played interview done by the seminar leaders, which was then analysed using the first interactogram. Invariably this promoted a lively discussion concerning the nature of a particular question or statement. Questions were easy to classify, although experience showed that the traditional split into leading/non-leading, open/closed questions is inadequate. Doctors often used the 'multiple choice question'; for example, "Do you think you're having problems because your work has been too difficult, or because your marriage is under strain, or because you are worried about your children at school?" where the patient has to respond to a forced choice. A different type of question is the 'multiple question' where the doctor asks a number of questions at the same time, leaving the patient to choose which will be answered. For example, "How have you been this week, have things worked out the way you expected, and have you had any side-effects from your medication?". The point was made during this discussion that there were no such things as 'good' or 'bad' interventions, but that some were effective and others counterproductive. Any strategy could have a use with certain patients at certain points in the interview. For example, direct leading questions, which are considered to be inadmissible by many, turned out to be used in practice by experienced therapists. They are inappropriate at the beginning of an interview where the interviewer is attempting to open up discussion, but they may be a perfectly acceptable way either of focusing on specific points of information or of establishing control in an interview which is getting out of hand. Statements fit less easily into neat categories, and during the evolution of our course we changed the labels on our statement 'pigeon-holes' several times. Discussion about classification made the trainees aware of statements that they used well and those that they used awkwardly or not at all. For example, some trainees never used empathic statements, while others employed so much polite social reinforcement that it became meaningless. Quite commonly trainees used nothing but questions in their interviews. When asked to role-play a patient being subjected to such an interrogative style of interviewing, many of them admitted that it felt like uncomfortable persecution.

An explicit aim was to encourage trainees to widen their range of basic skills. Time and time again trainees noted that they did not use 'silence'. They recognised that following even the slightest pause they intervened so quickly as to cut off any chance the patient might have had to think. Many admitted that they considered silence in an interview to be some kind of failure, although they could see there was no rational basis for this.

As well as building up a range of basic skills, trainees (and indeed the seminar leaders) became more aware of irritating idiosyncratic habits. A common example was the frequent use of a non-verbal utterance such as "ah-ah". Less common, although more damaging to the interaction, was the tendency for some therapists to answer their own questions!

Seminar 2

Very often, discussion of the first interactogram led the trainees to point out that the same intervention expressed with different emphasis or intonation might convey a very different meaning. This led on naturally to an examination of what the doctor was trying to achieve in this part of an interview. Therapist intent can be conveniently divided into information gathering, information seeking, catalysis, prescription, confrontation, catharsis, and support (Heron, 1975). Different basic skills were needed to achieve different intents at different points during the interview. An obvious example would be the use of a combination of open questions, silence, empathic statements, and reflections, in encouraging a patient to open up and explore a particular problem. Alternatively, a combination of feedback together with supportive statements might be an effective way of achieving a confrontation. When an interview was going wrong, trainees were asked to look first of all at what they were trying to achieve and secondly at what particular microskills they were using at the time. Garrulous or hypomanic patients often overwhelm the interviewer. A closer look at the microskills sometimes showed that skills appropriate for catalysis were being used, with the inevitable result! Another common difficulty was the trainee who grumbled that the patient seemed to run out of things to say. This was hardly surprising in the light of a microskills analysis which showed almost exclusive use of closed questions.

Seminar 3

By the time the trainees came to the third level they usually had become familiar with the task of looking at what they were doing in the interview rather than what their patients were doing. They were now asked to look not only at the question "What am I trying to do?" but "Why am I trying to do this?" Another way of approaching the same issue would be to ask the question "Why am I choosing to focus on this aspect of the patient's life rather than any of the other possibilities?" As a first step towards answering these questions we asked the trainees to 'brainstorm'. The object of this was to generate a number of alternative hypotheses to account for the patient's problems and symptoms. Such hypotheses could fairly easily be classified into the following categories: medical model; intrapersonal; interpersonal; and social. Alternative hypotheses were then discussed to see how much they were supported by information from the history or from observations in the sessions. If such evidence existed the hypothesis was termed a 'patient-focused hypothesis'. Very often we found little evidence to support an idea and we then had to conclude that the hypothesis came from the doctor's own head rather than being generated by the information available to him ('therapist-focused hypothesis'). A good example is the situation we termed the 'amateur psychoanalyst', in which appropriate and possibly damaging interpretations were made, often based on the latest book read by the trainee rather than on material presented by the patient. Examination of both the focus chosen by the doctor and the hypothesis used led easily to discussion of the way in which the doctor's own personality and experience was influencing interaction with the patient. Trainees were often intellectually aware of the meaning of countertransference but had not previously had experience of the way that it affected their own practice. Further evidence of this came from close analysis of sudden changes of style during an interview which at first instance appeared to be inexplicable. For example, a doctor by skilful and sensitive use of a range of microskills might encourage a patient to become emotional and to start to explore difficult and uncomfortable issues. Suddenly the tape-recording of the interview would document a dramatic change of style in that the doctor would revert to a traditional medical use of history-taking questions. Trainers were then able to ask the question, "Why at this particular point in the interview do you think you suddenly changed direction?" The other side of the coin, transference, could also be explored by following up similar openings.

Conclusion

We have run the Grammar of Psychotherapy courses for about 25 different groups of students. Most of the courses have been for trainee psychiatrists, but we have also taught other groups of paramedical personnel in both psychiatry and general medicine. Some of these courses were part of a study which compared students with matched control subjects. This allowed systematic evaluation of this teaching package, the results of which are now complete and will be reported in a subsequent paper.

Considering first the package as a whole, this was for many of our students the first time that they had ever listened to themselves talking to a patient. Laying aside for the moment the question of whether or not the specific items in our package were themselves of value, it did seem that the Grammar of Psychotherapy, with its individual 'interactograms', provides a framework which encourages trainees to tape-record sessions and then look critically at the way they interact with their patients. Merely listening to a tape of themselves can be for many trainees an intimidating and pointless procedure. However, by having to fill in an interactogram they are able to focus on certain issues which makes the process appear more worthwhile to them.

Informal feedback indicates that the course was well received by both students and clinical tutors. To quote:

> We normally do not write to individual lecturers thanking them for their contributions to our programme [statement] but in your case I feel I must write to thank you and say how impressed we all were with your series of lectures at Beechmont, St Francis Hospital. The trainees have found them extremely useful.
>
> [Silence]
>
> Our programme for next term is already arranged [another statement]. Do you feel you would like to come again to talk to the trainees during the autumn term [question]?

Courses were well attended. The structure enabled trainees to accept feedback and to involve themselves in lively discussion without feeling threatened. Surprisingly, some students gained insights into aspects of themselves through focusing attention on their own interactions with patients.

Many of the trainees attending our course are likely to go on to be general psychiatrists, and some will no doubt specialise in psychotherapy. Knowledge learnt through attending this course should be useful both to general psychiatrists and specialist psychotherapists.

In this course we avoided any particular theoretical stance and encouraged students to judge pragmatically whether a particular microskill or intervention was effective or not. The choice of course title was determined by the belief that the grammar of psychotherapy is the examination of the components that make up the relationship between therapist and patient, and that this is something that the plethora of schools of psychotherapy have in common.

The Grammar of Psychotherapy

Interactograms: Three Self-Monitoring Instruments for Audiotape Feedback

STUART LIEBERMAN and JOHN P. COBB

This paper describes the development of three self-monitoring forms to enable students to make constructive use of audiotapes of their interviews with patients. Each interactogram is described in detail, with examples where necessary.

The Grammar of Psychotherapy course is a method of teaching communication skills and elements of psychotherapy, as described in the accompanying paper (Cobb & Lieberman, 1987). An essential element of the course is supervised training supplemented by self-monitoring tasks. During development of the course, audiotapes were used in supervision. Listening to audiotapes without a structured method of attending to the material was found to be unproductive. Forms were designed that students completed in the privacy of their homes or offices while listening to the interviews which they audiotaped with patients. These forms focused the attention of the students on their interactional skills and psychological understanding. We decided that we would call the three self-assessment forms 'interactograms' because they are meant to examine the interaction between the doctor and the patient. Three interactograms were constructed.

Interactogram I

The first interactogram (Fig. 1) was inspired by various authors who have developed structured methods of teaching communication skills and interviewing skills (Beckvar, 1974; Maguire *et al*, 1978). We were particularly influenced by Ivey (1971), who trained students in the use of attending behaviour, minimal activity responses, verbal following behaviour, open enquiry, and reflection of feelings. He used the term 'microskill' to describe the discrete verbal and non-verbal components of an interaction.

The first interactogram was designed to examine in minute detail each actual intervention which the therapist uses when interviewing a patient. The interactogram is divided into three major sections: questions, facilitations, and statements.

Glossary of terms

Leading questions. These often sound more like statements than questions. They imply that the questioner expects a certain answer and make it difficult for the respondent to disagree. The tone of the voice can be as important in this respect as the form of words. Leading questions are widely used in the media and in court. They tend to have a somewhat bullying quality; for example, "You *do* agree with me, don't you?"

Non-leading closed questions. In contrast to leading questions, non-leading questions do not expect any particular answer. Closed questions usually begin with the words "Is", "Are", "Do" or "Did". They can usually be answered briefly or with a "Yes" or a "No". They help to focus a discussion but they are a deterrent to wider exploration of any particular issue. Examples are, "Do you usually get angry at your boss?"; "Is there a particular type of woman that causes you problems?"

Questions

Non-leading open
Non-leading closed
Leading (open or closed)

Facilitation

Silence (3 seconds)
Noises

Statements

Orientation/introduction
Reassuring
Encouraging/empathic
Summarising
Checking/seeking clarification
Focusing/scanning/prompting
Self-revelation
Other (specify)

Play through a tape of your own and classify each of your interventions according to the above list. Think for yourself what impact your particular style of interviewing is likely to have on this patient.

FIG. 1.

Non-leading open questions. These usually begin with "What", "How", "Why" or "Could". They cannot be answered simply by a yes or a no, and invite wider discussion. They can make the person questioned feel more at ease and make the discussion less like a cross-examination. Examples are, "How have you been over the past week?"; "Could you tell me more about how you feel now?"

Silence. Though long silences are anxiety-provoking and can lead to a sort of battle, short silences give people time to think. The most useful length of silence in an average interview is 4–10 seconds, which strikes a reasonable balance between the two extremes. Students were encouraged to see that this was a general guideline and not an absolute rule. They were asked to think about what function they wanted the silence to serve. Under certain circumstances the general guideline might be ignored. So, in controlling a garrulous subject it might be best to reduce silence to a minimum. In contrast, if the therapist wanted to raise the patient's level of emotion, or allow time for deep thought at a sensitive moment in the interview, then a long period of silence could be appropriate.

Noises. These can be used either to encourage or discourage the other person from continuing to speak. They include noises like "Ahha" and "Umm" as well as short phrases like "OK", "I see", or simply "Yes". All of these are useful if, like salt, they are used sparingly. The danger is that with overuse they become either irritating or just plain ridiculous. Trainees soon become aware of this when listening to themselves on audiotape. In all communications the tone of voice may be as important as the semantic content. This is powerfully illustrated by discussion of the tone in which 'noises' in this group were produced.

Orientation/introduction. This refers to the initial part of the interview, which helps to set the scene. Trainees were taught to introduce themselves; to spell out the purpose of the interview right at the beginning and describe the amount of time available for the session. An example: "My name is Dr Smith and I am a psychiatrist. We have an hour and during this time I would particularly like to talk to you today about important relationships. I also want to make sure that we have time for you to tell me about things that are on your mind right now. Before the end of the session I hope we will be able to make some plans about future treatment."

Reassuring. Reassurance (Wilcox & Salkovskis, 1985) is much used by doctors, although frequently it is ineffective either because it is over-used or alternatively because it is patently untrue. Having said this, most people like to be rewarded and also to be admired and respected. Confirmation that they are doing a worthwhile job is usually welcome. The danger with reassurance, and this was often picked up by students during feedback sessions, is that the patient, eager to please and receive approval, will start to behave like a circus animal. Only those things which are likely to produce a reward are described. Thoughts, attitudes, behaviour, and emotions which the patient fears will provoke disapproval are then kept hidden.

Encouraging. This refers to any statement which is aimed at getting the other person to talk more. Examples would be, "Please tell me more"; "Please expand on that"; "I really want you to tell me more about those aspects of yourself that cause you guilt, anxiety and pain"; "Please go on from here . . . anywhere you wish". Simpler encouragement statements include "Go on" and "That's good". As has been pointed out already, statement categories overlap. Thus a statement such as, "I can see this is very tough for you but I'd like you to try to explore this further if you can", is both empathic and encouraging. For the purposes of the interactogram the student was asked to classify the statement according to the predominant intent. Lively discussion around this point might fail to produce agreement concerning the 'correct' category, but would serve to increase awareness of the impact of a particular statement on a particular patient.

Summarising. These are statements which give a précis of what the speaker has said. Provided they are brief and to the point, they show that the listener has been concentrating on what has been said. They are also useful in allowing the doctor to collect his thoughts, and highlight what appear to be key themes in the patient's description. An example is, "So in the past few minutes you've talked about this terrible fear and you feel that it is to do with the feeling that you could lose control completely and end up in a mental hospital."

Seeking clarification. Only a genius can understand everything the first time it is heard and unfortunately there are few geniuses around. For the rest of us it is important to be prepared to ask for clarification when something in the other person's communication is unclear. For example, "I think that you view things like this . . .". Beginners often assume that to admit "I didn't understand that" is to show weakness which will lower the doctor's image in the patient's eyes. Usually the reverse is the case, as illustrated by the awkward interview in which an intelligent patient got more and more entangled in obtuse and mutually contradictory self-philosophising. The therapist, bored and exasperated, eventually blurted out, "I'm sorry, I don't understand what you are saying." Whereupon the patient laughed and admitted, "Neither do I, this is the way I always carry on when I am anxious." This proved to be the beginning of more useful communication.

Checking. The main purpose of a checking statement is to ensure that the gist of the other person's discussion has been understood. For example, "From what you told me I can see that you are pretty happy at the moment but there seems to be great difficulty when it comes to finding a suitable long term goal", or "As I understand it, the key issue for you is not so much the depression itself, but that as a result of it your family will reject you." At one level a checking statement simply aims to ensure that the therapist has understood correctly. During supervision discussion, however, students realised that such statements convey other intents, such as confrontation. For example, "So you are saying to me that there is absolutely nothing you do from the moment you awake until you go to sleep which gives you even the tiniest bit of pleasure or satisfaction!"

Focusing/scanning. People often talk in paragraphs. During the course of a paragraph several different subjects may be mentioned. The listener *scans* the paragraphs and then has the opportunity to select one of the points to *focus* on for further discussion. For example, a patient may have mentioned that he is tired, it has been a long day, work has been particularly difficult and that he was called out of bed in the middle of the previous night to look after his daughter. The listener may think it is a good idea to encourage the patient to talk a little more about his tiredness, and respond by comment along the lines, "I don't know how you keep going when you must be feeling very tired." Alternatively, if interpersonal issues are a major problem, then the therapist may decide to focus on the daughter: "How did you feel about disturbing your sleep for her?"

Prompting. This refers to any device which may encourage the speaker to continue talking along the same lines. A well used technique is to repeat the last word or phrase of the speaker's sentence. An alternative is 'the unfinished sentence'. Here the therapist starts a sentence but dries up part way through. The natural response is for the listener to complete the sentence and continue talking: "So the death of your father . . ." or "The pills you are having . . .".

Empathic. An empathic statement indicates that the speaker has some idea of what the other person is feeling. To be effective, empathic statements need to be accurate and may need considerable skill in interpreting both verbal and non-verbal cues. For example, "Yes, you feel you've just about had enough today", "You are on the verge of tears right now", or "I think for two pins you would like to bash someone on the nose at this moment." Empathic statements have a powerful effect in enabling a patient to express emotions, especially if used in the here and now. Inappropriate use can cause difficulties. Expressed empathy near the end of a session may lead to a flood of emotion which has to be cut off when time runs out. Too much empathy, especially over past events – "You have been through it"; "It must have been awful" – can come over as patronising, a caricature of a caring professional.

Self-revelation. Used with care, self-disclosure can be a powerful way of encouraging people to talk more about themselves. Such self-revelation must be honest, and in ordinary circumstances ought to be limited so as not to overwhelm the patient. Self-revelation can involve feelings that the therapist is experiencing at the time of the interview; for example, "You know I'm feeling a bit apprehensive because I realise you are angry about being brought into hospital against your wishes". Alternatively they can involve experiences in the therapist's own life which seem relevant to the patient's difficulties; for example, "When my mother died I thought I knew all about mourning and could work it through myself. It was only six months later when I was in a real state that I was finally able to listen to a close friend and accept that I needed help."

Use of interactogram I

Interactogram I was used by trainees to monitor – at a microskill level – interviews with patients which had been tape-recorded either on the ward or in outpatients. Trainees were asked to classify each intervention they made and to record it on the interactogram form. Five-minute samples were analysed in this way. Often in different interviews, with different patients (or role-played patients) in different settings, characteristic patterns emerged in their interactograms time and again. Such patterns could be described as 'interactive fingerprints'. A good example (Fig. 2) is the typical medical model pattern which is probably the product of traditional medical student training (Maguire *et al*, 1978). Once completed, the interactogram provided the basis for feedback. Each trainee was asked to comment on his or her own form and to note the range and frequency of microskills employed, before showing the interactograms to other members of the seminar for their observations. Feedback was pragmatic. Trainees were discouraged from saying that any particular style was "right" or "wrong". Rather, they were asked to consider the questions, "What is the likely effect on the patient of this combination of microskills?" and "Is this style appropriate for the task in hand?"

FIG. 2. Typical 'medical model' interactogram, characterised by predominant use of non-leading closed questions.

Interactogram II

Interactogram II (Fig. 3) builds upon the work done in the previous stage of training. During categorisation of the different types of microskill, trainees became involved with the question, "Why is this particular skill, or this particular group of skills, being used in this interview at this particular time?" Teaching thus focused on the topic of therapist intent. The second interactogram is a device to aid this and is based on the Six Category Intervention Analysis (Heron, 1975). Heron claims that the six categories provide a comprehensive framework for all intentions manifest during the course of an interaction with a patient. As such they constitute a powerful analytic training tool for anyone who wishes to build up skills, and particularly aid the development of self-assessment and self-monitoring in the helping professions.

The six categories are prescriptive; informative; confronting; cathartic; catalytic; and supportive.

Authoritative categories

Prescriptive, informative, and confronting intents are authoritative, that is to say it is the therapist who is taking the overtly dominant or assertive role.

Prescriptive. The intent here is to give advice or to evaluate, be critical or judgemental; a prescriptive intent is one that seeks to direct the behaviour of the patient, especially behaviour that is outside the therapeutic relationship; for example, "This evening I would like you to try and persuade your husband

INTERACTOGRAM II
[Microskills analysis of impact of therapist behaviour on patient]

Therapist intent	*Microskill*	*Focus*	*Effect on patient*
(Prescriptive, informative, confronting, cathartic, catalytic, supportive)	Question, statement etc.	Patient/therapist	Mild/moderate/strong positive or negative
(e.g. Catalytic)	(e.g. Self-revelation)	(e.g. Therapist)	(e.g. Mildly inhibiting)

Fig. 3.

to join us next week. Make a note of how the discussion goes so that even if he can't or won't come, we can talk about the way you set about approaching him over difficult matters."

Informative. The informative intent is to teach, to instruct, to inform, to interpret, to impart new knowledge and information to the patient. Although trainees recognise that 'lecturettes' are poor ways of putting across information, many fall into the trap of 'talking at' their patients and hoping for the best. Diagrams, booklets, charts may be used, and above all the therapist is encouraged to check that the patient has understood key information; for example, "Just tell me what your tablets are called, how many you are going to take and at what times?"

Confronting. This is to give direct feedback, to challenge, to try to alter the attitudes of belief or behaviour of the patient, in a sense to hold up a mirror to show the patient what he or she is like, either directly in regard to the relationship between the patient and the therapist or in the way in which the patient has behaved in the past or in the present outside the therapy situation. Confrontation can easily degenerate into a battle. The therapist becomes exasperated and angry, and the patient alienated and even more stuck with unproductive attitudes and patterns of behaviour. Effective confrontations help the patient to take a good look at himself, without feeling 'got at' by the therapist. Careful balance of microskills may be crucial in making the difference; for example, "Well, we have talked for about an hour. I can see you are very keen to get help. Symptoms have almost overwhelmed you in the past but you've shown a lot of courage in your struggle to keep going. Yet, despite your need and your efforts, two previous attempts at therapy have failed. Something in you seems to drive away therapists in the same way you have driven away other people in your life. History has a habit of repeating itself unless we learn from the past. So, to avoid this happening again with us, I want you to ask yourself the question – what is this destructive thing in me, which pushes people away and leaves me isolated and miserable?"

Facilitative categories

The next three categories are considered facilitative because the therapist is less obtrusive, more discreet, and seeks to elicit some kind of state of being in the client.

Cathartic. The intent here is to get the patient to feel, to show his or her feelings, to react with or abreact painful emotion, encouraging for example laughter, anger, fear, crying. The use of silence, in combination with empathic statements and non-leading open questions, is helpful in achieving this intent. Sensitivity to non-verbal cues is important. Sudden alteration in the tone of voice or faltering over a certain word alert the therapist that the patient is approaching a possible point of catharsis.

Catalytic. Here the intent is to enable the patient to learn and develop through his or her own self-direction. The therapist acts as a catalyst and allows a patient to explore his own problems and to then discover his own solutions. Rogerian counsellors (Rogers, 1961) make great use of certain microskills to achieve 'catalysis'. Repetition of the last word of the patient's sentence is so well known as to be parodied (Rhinehart, 1971). Noises, silence, summarising and checking statements are all typical of this mode of interviewing (Ivey, 1971).

Supportive. The intent here is to give approval, confirming or validating the worth, the value of the patient, as a human being. The therapist is not trying to promote change, although practical advice and information may be one of the ways of providing support. It usually helps a great deal if the therapist likes and respects the patient. Well-meaning attempts to provide support can founder if these qualities are lacking. Discussion of this, using audiotapes in combination with the interactogram, can lead to awareness of the ways that therapists give themselves away as far as their true feelings are concerned. This leads without difficulty into a discussion of counter-transference in subsequent seminars.

Use of interactogram II

Interactogram II records not only the therapist's intent but also links in the microskills being used to achieve this. Blow-by-blow analysis of material from a patient–doctor session, with intent in mind, shows that some of the therapist's expressed purpose in the interview is based on an evident plan in the therapist's mind. At other times the therapist appears to be reacting to material produced by the patient during the course of the session. Trainees were asked to think about this and record their observations on the form. Finally, they were asked to consider the effect on the patient in contentious cases; role-play was often helpful here. Again the criteria were pragmatic: "How well did the therapist achieve his aim?"; "How much did the patient benefit from this stage in the interview?".

During a short segment of an interview it is quite possible to have two or three different intents. For example, a general practitioner often includes several intents: to be informative, to support the patient, and to prescribe within a six-minute consultation. The major intent in a psychotherapeutic interview may be catalytic, with an underlying intent of support. The primary intent in a behaviour therapy interview could be prescriptive, with a preliminary confrontation.

Interactogram II is used in conjunction with interactogram I so that the students are able to discover what particular interventions they use to further their intents.

Interactogram III

Interactogram III (Fig. 4) is an analysis of the relationship process. This interactogram is designed to make the therapist aware that it is not only his or her microskills and intent which govern what happens in the relationship with the patient. There are other factors which play a part in any human interaction. We use the term 'macroskill' to mean those skills which are used throughout the entire interview and relate to the broader process of the interview. The third interactogram is divided into two major sections, the first of which is related to the hypothesis. This is considered a working assumption about the interview which the therapist uses to understand the basis for the interview or part of the interview. Junior doctors were encouraged to establish working hypotheses to help them understand the difficulties that they were tackling. Developing a hypothesis can be highly therapeutic to the patient; alternatively, it can provide the basis for a plan of action to be agreed between the patient and the therapist. A skilled therapist would be one who avoids making 'divine revelations', and instead provides a series of hypotheses: educated guesses or ideas which would be the basis for further discussion. For example:

(a) "From what you've told me in this first interview I can see that you have already found out that if you stick with your anxiety in a difficult situation, it starts to decrease after a short while. Now, I wonder if we could make this the basis for our plans to help overcome the phobias." (*Basis for behavioural work*)

(b) "I know your father died over two years ago but I wonder if in a sense you are still haunted by him." (*Invitation to look at possible psychological basis for symptoms*)

(c) "Over the past weeks we've been through a lot together and I think that you're already starting to wonder how you are going to manage without these regular weekly visits." (*Invitation to look at meaning of psychotherapeutic relationship*)

Hypotheses can be very broad or very narrow. A broad hypothesis might be the idea that the patient has a psychological problem, rather than a medical illness. A narrow hypothesis might be that the patient's depression is being projected on to him by his wife, who is actually depressed and with whose depression he is identifying. A hypothesis is not meant to be a revelation of profound truth but a basis for communication between the patient and the therapist. Essentially, it is meant to be an approximation that can be open to negotiation from either side. If it is not acceptable to the patient it could be discarded. There is a process of learning to develop hypotheses. This process begins with the ability to observe and listen to the patient. When feeling stuck in an interview, or wondering what to do next, attention to the patient can help the therapist to develop useful working patient-focused hypotheses. For example, "From the way you describe your previous treatment I guess you have really got little faith left in doctors", or "Your manner of talking makes me wonder if part of your problem lies in feeling that no-one can ever understand you."

The next stage in making a hypothesis lies in the ability to link what the patient is communicating with material from earlier in the sessions, or from previous sessions and past history; for example, "You know, we keep coming back to the worries that you have about what other people will be thinking of you, yet it is all guesswork because you never try to find out what they are really thinking."

From this the therapist may make suggestions of ways in which both he and the patient are behaving which is playing a central part in the interaction; for example, "You know, I think you find my manner irksome because you have never liked being told what

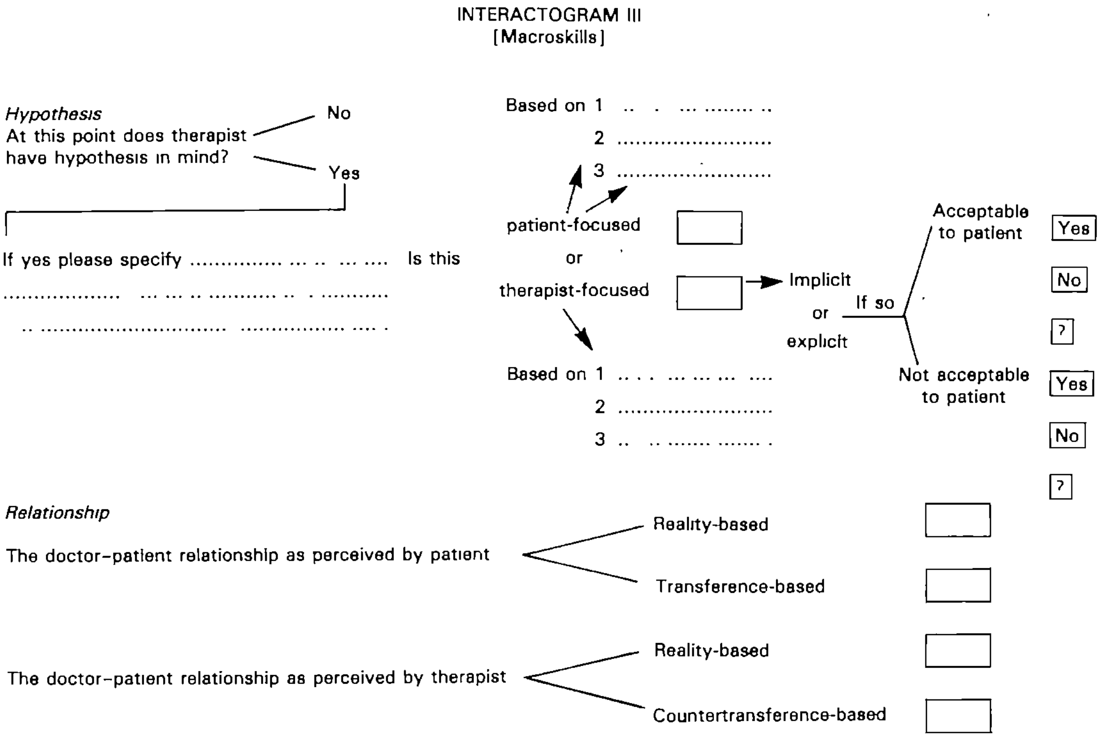

FIG. 4.

to do", or "We seem to be getting into difficulties and I think that may be because I have been encouraging you to think that I am going to take over responsibility for solving all your problems for you."

In the final stage the therapist starts to link what has been observed in the patient with his own theoretical ideas. These ideas come from watching other people working and from reading.

The number of different theories and the even greater number of individual variations of any one particular theory reflect the inventiveness of therapists in constructing hypotheses about the way in which their patients think, feel, and behave. If the therapist is more attentive to what is going on inside his own head than to what is going on inside the patient, the focus of the hypothesis will be therapist-based: "From my experience with other patients with anxiety like yours, I think . . .".

It is the ability and willingness to construct and use hypotheses which distinguish a psychotherapeutic style of interaction from plain interviewing. The skills can be most usefully acquired and developed by working with patients under supervision.

The second part of interactogram III focuses on the relationship between the doctor and the patient and introduces the concepts of transference and countertransference (Sandler *et al*, 1974). A number of factors influence the therapeutic relationship, both conscious and unconscious. The personality of the patient, the nature of the patient's difficulties, the personality of the therapist, the therapist's skill and experience, and the interaction between the patient and the therapist all play a part in defining the relationship. The doctor's ability to avoid imposing his own conflicts on the patient and distorting the material produced by the patient because of his own personality structure is an essential skill in the therapeutic encounter. Countertransference is both an essential part of therapy and an important phenomenon calling for self-awareness on the part of the doctor. We found that audiotapes of interviews, when specifically examined for evidence of countertransference, are a useful method of developing self-awareness.

Some aspects of patient and therapist are emphasised and other aspects minimised as the relationship develops. This process is unconscious and may be a re-enactment of previous patterns of relationship. The emphasis in the interactogram is that the relationship is a product of both participants, the doctor and the patient. What the doctor says and does and stands for are reacted to by the patient and vice versa, and an interpersonal feedback system quickly develops. This system must neither be ignored nor accepted blindly. The concept of transference is a special example of the way in which the feedback system operates when a patient reacts to the therapist as if he were representing some other person in that patient's past life, and the therapist is faced with what seem inexplicable responses to his words and actions. For example, one patient looked to a doctor as an authority on all subjects and depended on him to give advice on many areas of his life. This dependence and need for authority was a duplication of the nature of his relationship with his deceased father. He transferred his reactions from the relationship with his father to his relationship with the doctor.

By seeking information about past relationships, the therapist can identify the source of the transference. Without such knowledge the therapist can still be aware of the fact that the patient's reactions to the therapist are an unconscious re-establishment of some earlier relationship. The feedback system which develops between patient and doctor is a very important clue for the understanding of a patient's unconscious meaning. The reality-based perception of the doctor–patient relationship by both participants refers to the reason which brings together two participants in the interview: "We are here, you the doctor, I the patient, because I need help from you to deal with a particular problem or illness."

Conclusion

We believe that the use of these three interactograms is a helpful adjunct to psychotherapy supervision and provides a method for junior doctors to examine their audiotaped interviews with patients. This systematic approach, we believe, helps bridge the gap between traditional medical training and the psychotherapeutic approach which is an integral part of modern psychiatric practice.

Effectiveness of Time-limited Therapy Carried Out by Trainees

Comparison of Two Methods

B. BROCKMAN, A. POYNTON, A. RYLE and J. P. WATSON

Common neurotic and personality disorders account for widespread personal restriction and suffering. The need for effective, economically feasible treatment methods is widely acknowledged and the range of conditions successfully treated by available methods needs to be established. This study is concerned with two methods of brief psychotherapy; our aim was the essentially pragmatic one of investigating how far relatively long-term NHS out-patients with neurotic, personality, and interpersonal problems could be successfully and economically treated by the kind of therapists available in NHS settings. It is generally believed by psychoanalytically-oriented therapists that brief therapy requires high levels of training and experience; this is tested here, in that all the therapies were strictly time-limited, and none of the therapists had completed advanced training.

The research design differs from the currently favoured model of psychotherapy research in which an (ostensibly) homogeneous group of patients (usually suffering from depression) is exposed to a (supposedly) standardised therapeutic input. This model is somewhat remote from the realities of clinical practice and teaching, and ignores the extent to which groups of patients, however classified, differ importantly in respect of the issues addressed in therapy. Moreover, much current research employs a very restricted set of change measures. For example, most cognitive therapy research considers the mutual reinforcement of depressed thinking and depressed mood characteristic of the depressive cycle (Teasdale, 1983), but pays little attention to the life events and life strategies that predispose a person to become or remain depressed (Ryle, 1986). Psychotherapy and pharmacotherapy can both modify the depressive cycle, but psychotherapy, in most cases, seeks also to modify the patient's long-term interpersonal strategies and assumptions, his personality structure, and his self-attitudes, and measurement of these changes needs to be attempted.

In the study reported here, response to therapy was measured by using symptom inventories and also by measuring changes in assumptions and interpersonal strategies, using for this purpose a form of repertory grid technique reported in previous small-scale studies (Ryle, 1979*b*, 1980), and patients' ratings of individual targets. There is nothing innately illogical in this combination of nomothetic and ideographic measures, as Shapiro (1966) points out; exclusive reliance on the former in group studies can fail to detect the specific individual changes that are the aim of therapy.

Method

The patients' characteristics

The patients studied in the present research project were seen in the out-patient department of Guy's Hospital. Most were referred to the project by psychiatrists in the Guy's district; a small number were directly referred by GPs. The therapy and testing were completed by 48 patients, of whom 8 were aged under 25, 22 were aged 25–34 and 18 were aged 35 or over. Twenty-seven (56%) were receiving or had completed higher education or post-school professional training. These patients were classified retrospectively, from referral and research data, according to the Research Diagnostic Criteria (RDC). There were 37 (77%) who had had previous contact with psychiatric services, of whom 18 had received some form of psychotherapy. On referral, six patients were being treated with tranquillisers, seven were on tricyclics and one on MAOI antidepressant medication, and one was on a beta-blocker. The duration of the presenting complaint was as follows: 0–3 months, 7; 3–6 months, 0; 6–12 months, 9; 1–2 years, 10; 2–5 years, 12; over 5 years, 10. Thirteen patients completed pre-therapy assessment but did not complete the project. Of these, two did not accept the offer of therapy; two were taken out of the project and admitted for treatment, one for a manic and one for a depressive illness; one was taken on for long-term therapy and was subsequently admitted to hospital; four dropped out during therapy; and four failed to complete post-therapy testing.

The therapists and their supervision

Therapy was carried out by 15 different therapists: five trainee psychiatrists, with slight to substantial supervised therapy experience; six social workers, with varying amounts of casework experience but no formal therapy training; three nurses, one with a behavioural and two with a counselling training; and one trainee lay psychotherapist.

None had experience of time-limited therapy. On entering the project, a brief exposition of the two methods to be employed was offered, and it was recommended that two books describing the methods should be read (Mann & Goldman, 1982; Ryle, 1982); most attempted this. Weekly supervision in groups of 4–6 was the main learning method; this focused on general issues and on the specific features of the contrasting approaches.

The two therapeutic methods

All patients received 12 sessions of therapy, usually at weekly intervals. All were aware of the research component in the project. The two methods were labelled 'interpretive' therapy (INT) and 'cognitive-analytic' therapy (CAT).

The INT approach was based on the work of Mann (Mann & Goldman, 1982). This is a strictly interpretive, psychoanalytically based method, laying emphasis on the fact of termination and on the early formulation of a 'central issue'. This formulation aims to encapsulate the patient's 'chronically endured pain' in a description indicating the conflicts or assumptions related to it. Unlike the form of focusing employed by other brief therapists (e.g. Malan, 1976; Sifneous, 1972), this focus for treatment is shared with the patient, it being argued that accurate understanding conveyed in this way 'reaches through' the defences and engenders an early, intense involvement of the patient in the therapy. In this respect Mann's approach is closer to the CAT method than are other psychoanalytically-based methods.

The CAT approach (Ryle, 1979*a*, 1982) aims to integrate concepts and methods from psychoanalytic, cognitive, and behavioural schools. Focusing, or re-framing, is carried out with the patient, and an agreed, written list of target problems (TPs) and target problem procedures (TPPs) is formulated in the course of the first 3–4 sessions. A 'procedure' (Ryle, 1982) is the repeatedly used sequence of conscious and unconscious mental processes, including anticipation and feedback, which generates and monitors an individual's purposive acts and role behaviour. Neurotic procedures are characterised by being ineffective and resistant to revision. In formulating a target problem procedure (TPP), the aim is to identify the procedures causing and maintaining the patients' difficulties. The description of a procedure may refer to assumptions, beliefs, predictions about the efficacy and the consequences of the proposed actions, the choice of means, the action, and the evaluation of the outcome and consequences of the action. The 'Psychotherapy File' (see Ryle (1982) for an early version of this) was given to patients after the first or second interview. This includes instructions in self-monitoring of moods or symptoms, similar to those developed by Beck (1976), and descriptions of common TPPs, classified as Traps, Dilemmas and Snags, as in Ryle (1979*a*). A list of TPs and TPPs was agreed between patient and therapist at the fourth session. Patients were then encouraged to keep diaries recording their recurrence as a means of enhancing recognition and control, and they rated change on their TPs and TPPs on visual analogue scales at subsequent sessions. Therapists were free to employ a range of therapeutic methods, but all interventions were related to the issues summarised in the TPs and TPPs. Cognitive and behavioural methods were aimed at the processes described in these formulations, and interpretations of transference issues were made by reference to the TPPs.

TABLE I
Features of INT and CAT approaches

	INT	*CAT*
Early phase	Identify and name central issue	Patient self-monitors and reads therapy file
	Expect positive ± intense transference in most cases	Joint preparation of written list of TPs and TPPs
		Positive tranference plus active participation from patient
Middle phase	Ambivalent transference	Patient involved in learning to recognise TPPs (diary-keeping etc.)
	Interpret around central issue and termination	TPPs may manifest in transference
Termination phase	Transference recapitulation of earlier losses and disappointments	Continue TPP recognition; initiate change
		Termination transference issues linked with patient's new tools for self-help

Table I summarises the main features of the two treatment conditions. The psychodynamic issues interpreted in the INT approach were also considered in the CAT therapies, although their presentation and the therapeutic use made of them was influenced by the other activities included in the therapy.

No direct monitoring of the therapist interventions was carried out. Given that the formal instruction was minimal, it is likely that very variable levels of skill and compliance were displayed. However, the use of the psychotherapy file, instruction in self-monitoring and diary-keeping, the joint elaboration of written TPs and TPPs and the use of homework assignments were strictly confined to the CAT condition. With two exceptions, all therapists treated patients in both conditions, their first case being randomly allocated and subsequent cases being treated alternately in the two modes. A few more severe cases were allocated to the more experienced therapists; this allocation was made (by AR) blind to the mode to be employed.

Research design

Two hypotheses are being tested: (1) that patients will show significant improvement after 12 sessions of therapy carried out by relatively inexperienced trainees, and (2) (a null hypothesis) that no difference will be found between the two methods in respect of the type or degree of change. The basic design is summarised in Fig. 1. No waiting list or placebo control group was formed in view of the ethical and design problems involved in this group of patients, most of whom had long histories of symptoms and of treatment (see Shapiro, 1981). Given the brevity of the intervention, the long histories of most patients, and the specificity of the aims of therapy, it seems legitimate to attribute change, with respect to individually identified issues, to the treatment.

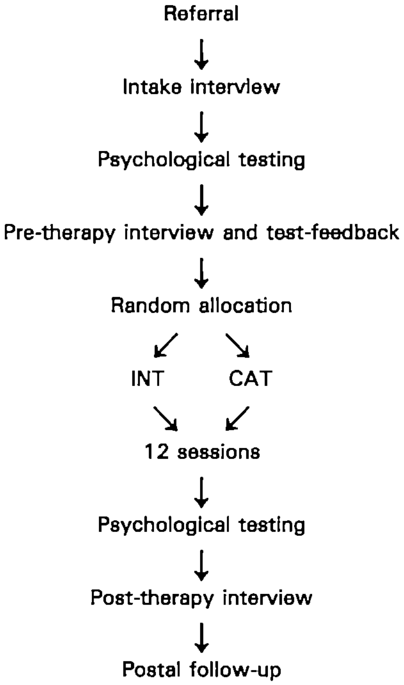

FIG. 1 Research design.

As regards the relative effectiveness of the INT and CAT methods, the use of the same therapists, the same testing and induction process, the same duration of treatment and random allocation provides a basis for attributing any differences found to differences in the therapeutic input. It should be noted that the two methods were supervised together; therapists' transfer of skills from one condition to the other would tend to diminish the contrast between the methods. It should also be noted that therapists were supervised by the originator of the CAT approach and this could be a source of bias.

In terms of psychotherapy research design, this project can be seen as an example of the 'dismantling' procedure (see Stiles *et al*, 1986) in which the CAT group received the full treatment and the INT group received this minus the cognitive, homework and written elements.

Procedure

Pre-therapy psychological testing

Testing was carried out by psychology students.

Symptom levels were assessed using three standard symptom questionnaires: the Beck Depression Inventory (BDI) (Beck *et al*, 1961), the 60-item General Health Questionnaire (GHQ) (Goldberg, 1972) and the Crown–Crisp Inventory (CCI) (Crown & Crisp, 1979).

Attitudes to self were measured from a semi-standard dyad grid of the form used in previous studies (Ryle, 1980). In this, patients rated their parents' relationship, and the role of self-to-other and of other-to-self in eight relationships (including with parents) and their relationships with themselves, on ten provided and six elicited constructs. The grids were analysed on the Ingrid program (Slater, 1972). A full account of this use of grid technique can be found in Ryle (1979*b*, 1980). Two measures of self-attitudes were derived as follows: the Positive Self Attitude Score (PSA) is the sum of the angular distances of the element self-to-self from the constructs 'looks after', 'respects' and 'forgives' (high score = low positive attitude); the Negative Self Attitude Score (NSA) is similarly derived from the constructs 'guilty to', 'blames' and 'is cross with' (high score = low negative attitude).

Specific cognitive change was assessed as follows. On the basis of the pre-therapy grid, predictions of desirable change were recorded for certain construct correlations. Some of an individual's assumptions about relationships are indicated by high or low construct correlations. Population norms for the angular distances between the constructs 'looks after', 'is dependent on', 'controls', 'gives in to' and 'is cross with' are available (Ryle, 1981). Where these values differed in a given patient's grid by more than one standard deviation from the norm, and where (as was usual) clinical data and discussion with the patient in the pre-therapy interview (see below) indicated that this was related to interpersonal difficulties, a prediction was recorded of the desirable direction of change. Other construct correlations, linked with the patient's specific problems and sometimes including the elicited constructs, were also, in some cases, made the subject of directional predictions. The grid prediction score (GPS) (see below) was derived in this way from the analysis of a grid of self-to-other elements only, in view of the fact that values in the self–other and other–self grids for these angular distances can differ considerably.

Pre-therapy interview

After initial testing, patients were interviewed (by AR). On the basis of the previous history and the assessment interview, and the discussion of the test results with the patient, a list of Research TPs and TPPs was drawn up with the patient, describing the problems and procedures which therapy was concerned to modify. This list was not identical with that drawn up by patient and therapist over the first four sessions in patients treated in the CAT condition, but obviously there was often close similarity with that list and with the 'central issue' identified in the INT condition patients.

Post-therapy psychological testing and interviews

After therapy, patients completed the same test battery and also the Therapy Experience Questionnaire (TEQ) (see Appendix 1). They were then interviewed (by AR) and they rated how far they felt they had resolved the issues identified at the pre-therapy assessment on the agreed list of Research TPs and TPPs. Rating was the change in millimetres on a ±20 mm visual analogue scale, of which the midpoint represented the level of difficulty at presentation; improvement scoring positively, deterioration negatively. From this was derived a mean TP and mean TPP score. The Grid Prediction Score (GPS) was derived by comparing the pre- and post-therapy grid values for the identified construct angular distances, counting predicted change as positive and the opposite as negative, and taking the mean of all predictions recorded.

Follow-up

Some months after completion, patients were contacted by post and were asked to repeat the tests and to indicate whether any significant life changes had occurred and whether they felt further treatment would be helpful. Unfortunately, for a number of reasons, the interval to follow-up varied from a minimum of 8 months to a maximum of 22 months.

Summary of research measures

The list of data available and coded on all patients at the start of therapy is given in Appendix 2.

Results

Comparability of the INT and CAT samples

Therapy and post-therapy testing was completed by 30 CAT and 18 INT patients. This discrepancy in numbers is partly a reflection of the higher attrition rate in patients in the INT sample (7 of the 11 non-completors who had started therapy were INT patients), but is largely due to chance in the balance of methods used by therapists seeing odd numbers of patients. The attrition group had higher mean initial symptom scores than did patients completing the project (BDI 24.2, GHQ 29.0, CCI 56; see Table IV for the lower values of the treated patients in the CAT and INT samples). The distribution by diagnosis in the INT and CAT samples (Table II) is relatively similar; in view of the small numbers in most of the categories, no breakdown by diagnosis is offered in terms of outcome. Despite the random allocation, indications of greater severity were more frequent in the CAT sample, as follows.

TABLE II
Diagnosis of CAT and INT samples

Diagnostic category on RDC	*CAT*[1]	*INT*	*Total*
1. Minor Depressive Disorder	12	3	15
2. Minor Depressive Disorder with significant Anxiety	11	8	19
3. Intermittent Depressive Disorder	0	1	1
4. Recurrent Unipolar Major Depressive Disorder	1	0	1
5. Generalised Anxiety Disorder	3	1	4
6. Generalised Anxiety Disorder secondary to Phobic Disorder	0	1	1
7. Obsessive Compulsive Disorder (one with Minor Depressive Disorder, one with generalised Anxiety)	2	1	3
8. Other Psychiatric Disorder (Bulimia Nervosa)	2	0	2
9. Alcoholism, plus Minor Depressive Disorder with Anxiety	1	0	1
10. Never Mentally Ill	1	3	4

1. CAT sample includes three cases with two diagnoses: i.e. Minor Depressive Disorder and Obsessive–Compulsive Disorder; Generalised Anxiety Disorder and Bulimia Nervosa; Minor Depressive Disorder and Bulimia Nervosa.

Medication. On entry to the project, four of the INT patients were on minor tranquillisers. Of the CAT sample, two were on minor tranquillisers, one was on a beta-blocker, one was on a MAOI and seven were on tricyclics. Treatment aims included reducing or ending tranquilliser use; antidepressant medication was usually continued. No patients were started on medication after referral.

Age. The proportion of patients aged over 35 was higher in the CAT sample.

Obsessionality. All but one of the 13 patients scoring 11 plus on the CCI obsessionality scale were in the CAT group ($\chi^2 = 6.33$, $P < 0.05$).

Scores. Mean BDI and CCI scores were higher in the CAT sample, but GHQ scores were marginally lower (see Table IV).

Patient characteristics associated with outcome

In order to investigate the influence of age, sex, education, duration of symptoms and initial inventory scores on outcome, patients were divided into response and non-response categories on five outcome measures. The criteria used were such that approximately one patient in three was classed as non-responding. The criteria of response were as follows.

Symptom response was measured by dividing initial scores into four categories on both the BDI and the GHQ (0–13, 14–20, 21–26 and 27 plus); failure to go down to a lower category at post-testing (unless initially in the lowest), on either inventory, was classified as non-response.

TABLE III

Relations between initial patient characteristics and outcome measures significant at 10% or better

Patient characteristics and baseline scores	*Outcome measures*	*Association*	χ^2	P<
Age 35+	PSA improvement	–	4.67	0.05
	NSA improvement	–	5.61	0.05
	Symptom response	–	3.06	0.1
Symptoms over 5 years	PSA improvement	+	3.57	0.1
Initial BDI 20+	PSA improvement	–	3.36	0.1
	NSA improvement	–	2.86	0.1
Initial GHQ 34+	Target ratings	–	2.73	0.1
	PSA improvement	–	7.99	0.01
Initial CCI–T (total) 45+	Symptom response	–	4.75	0.05
Initial CCI–O (obsessionality) 11+	Symptom response	–	3.37	0.1

Target rating improvement response was defined as a score of +5 or more on both TP and TPP ratings.

Grid Prediction Score response was defined as a GPS of plus 20 or more.

Positive Self Attitudes response was defined as a PSA score reduction of 20 or more (indicating more positive self-attitudes).

Negative Self Attitudes response was defined as a NSA score increase (indicating less negative self-attitudes).

The associations between patient characteristics and response to the five measures were tested using 2×2 χ^2 tests; associations significant at 10% or better are listed in Table III. Neither sex nor education were related to outcome on any measure at this level of significance. The seven patients with histories of less than 6 months showed similar changes to those with longer histories; the greater improvement on one measure of long term patients is surprising. The other associations are expected; older patients and iller patients showed less change.

Relation between outcome measures

Rank order correlations between the TP, TPP and GPS scores and changes in the PSA and NSA showed only one association significant at the 5% level: that between mean research TP and TPP ratings ($r=0.84$). A sum score was derived from the different response/non-response categories using the criteria listed above. Scoring 1 for response and 0 for non-response, patients could achieve a 'sum score' of 0–5 from symptom response, target rating response, GPS, PSA and NSA scores. It seems reasonable to assume that patients showing improvement in more of these independent measures will have benefitted more from therapy. This sum score was significantly correlated with high TEQ scores indicating a positive evaluation of therapy by the patient ($\chi^2=7.9$, $P<0.01$).

Comparison of change measures in INT and CAT patients

Nomothetic measures

Pre- and post-therapy mean scores for five measures are given in Table IV. Mean scores on the BDI and GHQ dropped significantly in both INT and CAT samples. CCI total score dropped significantly in the CAT sample. Patients in the CAT group showed significant improvement in PSA scores. Improvements in NSA (reflected in larger scores) did not reach significance in either group.

TABLE IV

Pre- and post-therapy mean scores for CAT and INT samples on five nomothetic scores

CAT (n=30)	*Pre-therapy mean*	*Post-therapy mean*	*Significance (Wilcoxon)*
BDI	17.0	12.4	$P<0.01$
GHQ	22.5	13.7	$P<0.02$
CCI	45	33	$P<0.01$
PSA	325	276	$P<0.01$
NSA	190	214	NS
INT (n=18)			
BDI	10.8	6.7	$P<0.01$
GHQ	24.7	9.3	$P<0.01$
CCI	34	31	NS
PSA	288	272	NS
NSA	186	192	NS

Ideographic measures of change

Mean TP and TPP ratings and GP scores are given in Table V for three groups, namely INT and CAT patients, and a sample of CAT patients matched with the INT group on initial BDI and CCI–O (obsessionality) scores. TP and

TABLE V

Mean scores on three ideographic change measures for INT, CAT, and matched CAT samples

Sample	*INT (n=18)*	*CAT (n=30)*	*Matched CAT (n=17)*	*Significance of difference between INT and CAT*
TP	10.6	8.7	10.6	$P<0.01$
TPP	11.1	9.7	11.1	$P<0.01$
GPS	23.6	33.0	33.2	$P<0.01$

TPP ratings are significantly higher in the INT than in the whole CAT sample, but no different from the scores found in the matched CAT sample. GPS scores are the same in the matched and unmatched CAT samples, being significantly higher than in the INT sample.

Comparative effect of INT and CAT methods

It has been shown, starting from different initial mean score levels, that both INT and CAT samples showed significant reductions on BDI and GHQ scores, and the CAT sample also showed significant reductions in CCI-T (total) scores. When matched on initial BDI and CCI-O (obsessionality) scores, the two approaches had the same effect on TP and TPP ratings; the more depressed and obsessional CAT patients, excluded in this matching process, did less well. The mean GPS score was higher for CAT sample patients and was independent of the initial symptom level. The effect size of the CAT over the INT sample in improving self-attitudes was calculated using the formula proposed by Smith & Glass (1977), whereby effect size equals difference in mean change between the samples divided by the standard deviation of the INT sample. The value of this was 1.0 in respect of changes in PSA scores, but when patients with initially high scores (336+) were omitted, to give a sample matched on initial PSA (mean 290), the figure became 0.53. For the NSA, where pre-therapy levels were similar in CAT and INT patients, the effect size was 0.38. The standard deviations of construct angular distances are in the range 17–25 (Ryle, 1981); on this basis the effect size in respect of the GPS approaches 0.5.

The mean sum scores (see above) were 3.7 for the CAT sample and 3.1 for the INT sample ($t=4.3$, $P<0.02$). This difference reflects similar effectiveness in symptom reduction and target problem ratings, and a greater effect of the CAT approach in modifying specific cognitive features expressing individual assumptions about relationships and in altering attitudes towards the self.

Follow-up

Postal follow-up was attempted on all patients, but satisfactory returns were received from only 25 (62%), due to address changes and some refusals. The time from end of therapy to follow-up was variable (INT sample range 6–22 months, mean 14; CAT sample range 8–18 months, mean 12). The mean score values on seven measures of the whole sample post-therapy, and of the follow-up sample post-therapy and at follow-up, are given in Table VI. The follow-up sample's mean scores post-therapy were virtually the same as the scores of the whole sample. A small deterioration in mean scores between post-therapy and follow-up testing was recorded on two measures in both the INT sample (BDI and GHQ) and the CAT sample (GHQ and NSA); improvements in mean scores, of modest size, were recorded on the remaining measures. The two worst outcomes, showing improvement from presentation to follow-up on only one measure, were in men aged over 35 with initial CCI–O scores of 11 or more.

Discussion

In the use of individualised goal and outcome measures, in the degree to which treatments, therapists and patients are described, and in the use

TABLE VI

Post-therapy and follow-up mean scores of INT and CAT samples

	n	*BDI*	*GHQ*	*PSA*	*NSA*	*GPS*	*TP*	*TPP*

Whole sample post-therapy	30	12.4	13.7	276	214	33	9	10
Follow-up sample post-therapy	14	12.6	12.5	273	218	31	8	9
Follow-up sample at follow-up	14	10.4	17.8	240	201	34	9	10

of diverse outcome measures, the design of this study is in accordance with the recommendations of Fiske *et al* (1970). It would, however, have been strengthened by the inclusion of independent assessments of change.

The INT and CAT methods of treatment chosen for comparison were intentionally similar in important respects, both being characterised by brevity and by the sharing of the focus with the patient, both being preceded by the same assessment process and the treatments being carried out by the same therapists. The therapists' prior experience and outlook were fairly equally spread along the active versus interpretive spectrum. Both INT and CAT approaches involved them in the unfamiliar task of producing, after 3–4 sessions, formulations encapsulating the issues to be addressed by the therapy. This task, and the research component in the project, probably served to heighten therapist involvement. Patients in both conditions had the same experience of psychological testing and received feedback on these procedures; it is likely that this (largely cognitive) input had some therapeutic effect. The CAT approach differed, firstly, in the use of written material; secondly, in the form in which the issues addressed in the therapy were formulated; thirdly, in the involvement of patients in serial ratings of change on the defined issues; and fourthly, in the inclusion of cognitive/behavioural tasks in the therapy, notably self-monitoring of identified TPPs. These additional factors could be seen to maximise the pressure on patients to accept responsibility for their defined problems (Försterling, 1980; Keller, 1984). While therapists avoided direct advice, they were more active in the CAT mode in offering concepts and setting cognitive behavioural tasks designed to help the patient initiate change, and in these respects offered more of the factors associated with positive outcome according to Murphy *et al* (1984).

Unfortunately the random allocation of patients between the two modes produced poorly matched samples, the bias being in the direction of the CAT sample being more severe. The choice of outcome measures was determined by the conviction that therapy should affect both the presenting symptoms and difficulties complained of by the patient, and the underlying 'dynamic factors' reflected in these complaints. While measures of these two sorts of change may co-vary to a degree (Mintz, 1981), at least in the short term, it was considered that the underlying assumptions and strategies about self and relationships were the most appropriate target for therapeutic change. Attempts by psychoanalytic researchers to assess these factors clinically have been of low reliability (DeWitt *et al*, 1983). In the present study the repertory grid has been used to yield measures related to the 'dynamic' issues, in line with the general work reviewed by Ryle (1976), and the specific applications of this grid method to previous outcome research reported by Ryle (1979*b*, 1980). The measurement of positive and negative self-attitudes, achieved by embedding the element self-to-self among the range of self-to-other and other-to-self elements in the dyad grid, provides indications of change in self-attitudes. The GPS represents a specific ideographic measure of the patient's changing of identified, non-adaptive, idiosyncratic assumptions, in most cases concerning the relationship between control, looking after, dependency, anger, and giving in. The psychological processes indicated by these identified construct correlations, about which predictions of change were made, can be seen to be those described as dilemmas (Ryle, 1979*a*, 1982), and, in object–relations terms, as related to splitting and projective identification.

The evidence for the overall efficacy of these two forms of brief therapy rests on the comparison of the 'before' and 'after' measures. Given the relatively long duration of presenting problems in most cases and the individualised nature of some of the outcome measures, it seems reasonable to claim that both approaches were effective in a substantial proportion of the cases treated. Significant changes in many group mean scores occurred between pre- and post-therapy testing; these were maintained but did not show further significant change in the period between post-therapy testing and follow-up, a period which was longer than the duration of therapy itself. As regards the relative impact of the INT and CAT approaches, the evidence suggests that in cases of equivalent severity the two approaches have an equal impact on symptoms and self-report ratings, while in all cases, independent of severity, the CAT approach had a greater effect on some grid-derived measures of cognitive change. As therapists were supervised in both modes by AR, the possibility of biased supervision must be acknowledged. However, the supervision of dynamic issues was common to both conditions. It is more likely that any advantage of the CAT approach was minimised by the design, in that therapists working in the INT condition may have been influenced by their CAT training, and patients in the INT condition had experienced cognitive input during their test completion and pre-therapy interview.

Luborsky *et al* (1980) concluded that prediction of outcome of psychotherapy is difficult; it is rare to demonstrate associations between pre-therapy measures and outcome strong enough to be of any clinical value. This is true of the present study. It is, however, noteworthy that neither educational level nor duration of symptoms were related to therapeutic response. That some patients of greater age, higher obsessionality and higher symptom scores at outset did less well is worthy of note, and suggests that the response to treatment of patients with these features should be carefully monitored; it is possible that longer or different intervention may be indicated.

As a result of the research reported here, the CAT approach is being further evaluated, but with some changes in practice, notably the following.

Firstly, therapists attend a two-day training workshop. This lays particular emphasis on the process of reformulation as it is our impression that, if this is adequately carried out, therapists of relatively little experience can combine therapeutic methods effectively, and can make use of transference when appropriate, within the terms outlined by the target problem procedures.

Secondly, it is considered that patients showing major depressive symptoms should be treated pharmacologically before psychotherapy is commenced, and failure of less severe depression to recede after the first few sessions is also taken as an indication for medication (see DiMascio *et al*, 1979). Thirdly, the meaning of common psychosomatic and mood symptoms can often be decoded early in therapy with the use of self-monitoring, but some patients with more structured disorders (e.g. severe eating disorders, obsessive–compulsive disorders) may require a more energetic treatment of the symptom before the underlying issues can be addressed in therapy.

Fourthly, while the approach is usually adequate for crisis intervention or for patients with common neurotic disorders, patients with poorly integrated personalities will usually need more than a brief intervention. However, even with this group of patients, a time-limited approach has many advantages as a first therapy, providing an opportunity to see how much use patients can make of which aspects of therapy, while guarding against the risk of regression. In such cases the initial 'package' of therapy will not attempt to address all the identified problem procedures.

We believe that the CAT approach, with its demand on both therapist and patient for early conceptual work in describing accurately the repeatedly used, ineffective procedures underlying the patient's difficulties, is an effective therapeutic method and one which provides a suitable framework for trainee psychotherapists and a good basis for training general psychiatrists in psychotherapy. Further research will aim to identify with increasing accuracy the features which can be identified at different stages of the therapy that may indicate the possibility of briefer, or the need for more extended, or different, forms of treatment.

Acknowledgements

Participating therapists were B. Brockman, P. Cowmeadow, A. Faulkner, J. Kerridge, N. Maple, P. Meredith, J. Mounty, S. Norrington, P. O'Hanlon, A. Poynton, S. Price, J. Revell, A. Segal, H. Thomas and D. Tossall.

We are grateful to the following psychology students who carried out the testing of the patients: Tony Kyriakides, John Leary, Hla Myat-Saw, and Walter Wills.

Appendix 1
Therapy Experience Questionnaire

The Therapy Experience Questionnaire is reproduced in Table VII. There are four four-item subscales, items being presented in turn

for therapist warmth (W), therapist respect (R), therapy as a learning experience (L) and therapy as a feeling experience (F). The first two subscales were modified from Strupp *et al* (1969). The L and F scales were selected, after piloting, on face value, with the aim of exploring whether the more 'cognitive' CAT approach was sensed by patients as involving less feeling and/or more learning. Each item scores 1–5. Mean values on the INT and CAT samples are shown in Table VIII.

TABLE VIII
Mean values on the INT and CAT samples

Sample	*n*	*W*	*R*	*L*	*F*	*Total*
INT	18	16.6	17.2	16.5	15.8	66.1
CAT	28	17.5	17.7	16.5	16.2	67.9

Appendix 2
Summary of research measures

1. Age: (classified as <24, 25–34, 35+).
2. Sex.
3. Education (EDN-coded tertiary education or equivalent training, or not).
4. Duration of presenting problem (DTP-coded as under 3 months, 3–6 months, 6–12 months, 1–2 years, 2–5 years, over 5 years).
5. Score on Beck Depression Inventory (BDI).
6. Score on General Health Questionnaire (GHQ).
7. Score on Crown–Crisp Inventory (total – CCI-T).
8. Score on Crown–Crisp Inventory (obsessionality subscale – CCI-O).
9. Positive Self-attitude Score (PSA).
10. Negative Self-attitude Score (NSA).

Measures 5–10 were repeated at the post-therapy testing, at which point the following were available in addition:

11. Grid Prediction Score (GPS).
12. Research Target Problem rating (mean – TP).
13. Research Target Problem Procedure rating (mean – TPP).
14. Therapy Experience Questionnaire sum score (TEQ).

The DSM–III Concepts of Schizophrenic Disorder and Schizophreniform Disorder

A Clinical and Prognostic Evaluation

ROGER O. A. MAKANJUOLA and SUNDAY A. ADEDAPO

Consecutive new patients presenting at a Nigerian psychiatric unit over a 14-month period and fulfilling the DSM–III criteria for schizophreniform disorder, (active) schizophrenia and residual schizophrenia were studied. There were no differences between the three groups with respect to background social data. The schizophreniform patients had a lower incidence of previous psychotic episodes. There were no differences between the first two groups with respect to the distribution of PSE symptoms and signs, Schneider's First Rank Symptoms, or severity of psychopathology. Initial clinical outcome, and longer-term clinical and social outcome, assessed 25–38 months after index presentation, was best in the schizophreniform patients and worst in the patients with residual schizophrenia. The findings are consistent with schizophreniform disorder lying on a spectrum of schizophrenic disorders. They also highlight inadequacies in mental health services in Nigeria and other developing countries.

The third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM–III; American Psychiatric Association, 1980) makes a distinction between schizophrenic disorder and schizophreniform disorder; a duration of at least six months is required for the former, and between two weeks and six months for the latter. This distinction highlights the controversy over the possible existence of a separate disorder of short duration which, although manifesting with schizophrenic symptoms, carries a better short-term as well as long-term prognosis than schizophrenia *per se* (Langfeldt, 1937; Slater & Roth, 1969; Smythies, 1973; Spitzer *et al*, 1978; Fox, 1981). An alternative approach would be to view such a disorder as a form of schizophrenia which because of its relatively acute nature and earlier presentation would respond more rapidly and more favourably to treatment. The DSM–III categorisation does not differentiate between a schizophrenic patient who has been ill only for a short period up to the time of diagnosis and 'schizophreniform disorder' (assuming the latter actually exists). The above consideration might appear to make the term schizophreniform disorder meaningless in terms of therapeutic implications.

The present paper describes a study of consecutive new patients presenting at a psychiatric unit over a 14-month period, in whom the diagnosis of schizophrenic disorder (active or residual) or schizophreniform disorder was made. The three groups were compared in an attempt to detect any differences, apart from duration of illness, between them.

Method

Consecutive new patients presenting at the psychiatric unit of the Wesley Guild Hospital, Ilesa, Oyo State, Nigeria between 1 November 1982 and 31 December 1983, and in whom a diagnosis of schizophrenic disorder or schizophreniform disorder was made according to DSM–III criteria, were studied. The schizophrenic patients were further categorised into those with active symptoms and those with residual schizophrenia, according to the DSM–III criteria.

For each patient, a psychiatric case-history was taken and a full mental state and physical examination carried out. Background data were collected on a specially prepared *pro forma*. The Present State Examination (PSE; Wing *et al*, 1974) and a World Health Organization modification of the Brief Psychiatric Rating Scale (BPRS; Overall & Gorham, 1962) were also administered. The modified BPRS contains three items additional to the original 16 – for pressure of speech, excitement, and disorientation. Where the patient was too disturbed for the PSE to be administered fully on presentation, sections 18–20 for observed behaviour, affect, and speech were administered and the other sections administered later, in all cases within one week. Specific note was made of the presence of those First Rank Symptoms (Schneider, 1959) which are not clearly differentiated in the PSE. Other data were also collected over a series of interviews in some cases. The first author was the consultant responsible for the management of all the patients studied.

Between 25 and 38 months after index presentation, the patients were traced and re-examined. Although a

TABLE I

Background data in the three groups of patients[1]

	Schizophreniform disorders (n = 34)	*Active schizophrenia (n = 66)*	*Residual schizophrenia (n = 16)*

proportion of them were currently attending the psychiatric unit at the time, the majority had to be contacted in the community. This involved journeys to 21 different towns, the furthest being 110 km from the psychiatric unit. At the follow-up interview, information was obtained both from the patient and, where possible, from the relatives. In the nine cases where the patient was dead, information was obtained from relatives. Such information was supplemented from the patients' case files. A specially designed *pro forma* for recording details of occupation, marital, family, and social data as well as clinical course was used. In addition, a full mental state and physical examination was carried out. The PSE and modified BPRS were administered and the Clinical Global Impression (McGlasham, 1973) was recorded.

All interviews and evaluations were carried out by the first author, both at presentation and follow-up. No other

Note. None of the differences was statistically significant (χ^2 test).

adequately skilled and trained personnel were available in the psychiatric unit; a reliability check on the DSM-III diagnoses was therefore not possible.

Results

There were 66 patients with active schizophrenic disorder, 16 with residual schizophrenia, and 34 with schizophreniform disorder. Background data (Table I) indicate that in addition to the significantly greater duration of illness among the schizophrenic patients ($P<0.01$) there was also a significantly greater number of previous episodes of the disorder among the two schizophrenic groups ($P<0.01$).

Clinical features

The frequencies of the most common PSE symptoms and signs in the schizophreniform and active schizophrenic groups are given in Table II. There were no apparent differences between the two groups. There was a somewhat higher frequency of occurrence of Schneider's First Rank Symptoms in the schizophreniform group (not statistically significant) (Table III). In both groups the experience of voices arguing about or discussing the subject in the third person was the most common, followed by 'made' volitional acts.

The clinical severity of the disorder, as estimated by modified BPRS scores, was similar in both groups with active symptoms, mean score ± s.d. being 30.0 ± 10.1 in the active schizophrenic group and 31.6 ± 8.9 in the schizophreniform group. There were no differences in the occurrence of a history of drug abuse (13 in the active schizophrenic, four in the residual schizophrenic, and five in the schizophreniform group). Only four active schizophrenics, two residual schizophrenics and three schizophreniform patients had a positive family history of mental disorder.

Initial clinical outcome

The initial clinical outcome, as determined by the interval between presentation and complete disappearance of symptoms, was much better in the schizophreniform group and worse in the residual schizophrenics (Table IV).

Outcome at 25–38 months

Only a small proportion of patients attended follow-up clinic regularly. The majority defaulted within six months (Table IV). In a number of cases, patients who had defaulted resumed attendance, usually after relapse.

Out of the original cohort of 116 patients, the authors were successful in tracing 94 cases (84%), made up of 31 (proportion 0.9) of the schizophreniform group, 51 (proportion 0.8) of the active schizophrenic group and 12 (three-quarters) of the residual schizophrenic group, at between 25 and 38 months after index presentation. Mean interval ± s.d. between initial presentation and follow-up interview was 31.8 ± 3.9 months in the schizophreniform group, 31.9 ± 3.9 months in the active schizophrenic group and 32.2 ± 4.1 months in the residual schizophrenic group (ANOVA, $F=0.025$, NS). Proportions 0.4 of the schizophreniform group, 0.7 of the active schizophrenic group, and 0.5 of the residual schizophrenic group had further episodes of active functional psychosis, usually of schizophrenic type (Table IV). These differences were statistically significant for further active schizophrenic episodes but not for further active psychotic episodes overall. (Some episodes diagnosed as 'atypical psychosis' were probably schizophrenic in nature, but this could not be ascertained because of inadequate information.) In addition, six of the active schizophrenic group and eight of the residual group continued to suffer from residual schizophrenic symptoms. There were no significant differences in the incidence of physical problems (Table IV).

TABLE IV

Clinical outcome over 25–38 months after index presentation: except where indicated, figures refer to the 94 patients contacted at 25–38 months

	Number of patients			*Statistical analysis*
	Schizophreniform group	*Active schizophrenic group*	*Residual schizophrenic group*

Continuous (no defaulting)	6	5	4	
Over 12 months	4	6	4	
6+ to 12 months	3	16	2	
6 months or less	18	36	6	
Transferred to another unit	3	3	—	

[1] Did not recover within 6 months.

[2] Died during course of illness after defaulting; cause of death unknown.

[3] Persistence of residual schizophrenic symptoms beyond one year after index presentation.

[4] Excluding insomnia, which occurred at some stage in almost all patients.

Four of the schizophreniform and five of the active schizophrenic patients had died. One (a schizophreniform patient) had died during the index episode, of unknown causes, having defaulted from treatment. Another schizophreniform patient committed suicide. One schizophreniform and one schizophrenic patient had been beaten to death by night guards who had found them wandering, following relapse. The other five patients had died in traditional healers' establishments following relapse. It is very possible that some of those who could not be traced had also died.

At follow-up, the great majority of the schizophreniform and active schizophrenic groups were not receiving any form of treatment in a psychiatric unit. At the follow-up interview, a significantly higher proportion of the schizophreniform group were without any current mental disorder and a significantly higher proportion were not suffering from active psychotic features (Table V). The schizophreniform group also scored lower on the two indices of psychopathology employed, the modified BPRS (not statistically significant) and the Clinical Global Impression ($P < 0.05$).

TABLE V

Current clinical situation in the 94 patients evaluated at 25–38 months after index presentation

[1] Neurotic disorder or non-specific symptoms.

The prognosis with regard to recovery of social and occupational functioning was distinctly better in the schizophreniform patients. These differences were statistically significant in terms of interval between index presentation and resumption of work (or school), of whether the individual was currently working at the time of follow-up interview, and of difficulties in family and social relationships, but not in marital relationships (Table VI).

Discussion

Since Kraepelin and Bleuler described schizophrenic disorders at the beginning of the century, their diagnosis has always carried the implications of chronicity and poor prognosis. Suggestions that a more acute disorder with similar symptoms might carry a better prognosis were formalised in the description of 'schizophreniform psychoses' by Langfeldt (1937). This concept has been incorporated into DSM–III. However, Langfeldt's concept of schizophreniform disorder is somewhat different from that of DSM–III, which is employed in this study. Langfeldt described an acute disorder with an obvious precipitant, marked by prominent clouding of consciousness and affective, hysterical or paranoid colouring as well as typical active schizophrenic symptoms. The ICD–9 (World Health Organization, 1978) concept is similar to that of Langfeldt. DSM–III differentiates schizophrenia from schizophreniform disorders merely on the basis of duration of symptoms. In fact it is likely that there is considerable overlap between these different concepts of schizophreniform disorder.

In the present study, apart from the longer duration of current illness among the two schizophrenic groups compared with patients suffering from schizophreniform disorder at the time of index presentation, there was also a significantly greater number of patients with a history of previous psychiatric episodes among the schizophrenic patients. However, the two groups with active psychotic symptoms (the schizophreniform and active schizophrenic groups) did not differ significantly in terms of degree of psychopathology, frequency of PSE symptoms, or signs or frequency of First Rank Symptoms.

Patients with schizophreniform disorder had a much better prognosis than the two schizophrenic groups in all parameters employed. This included

initial clinical outcome, clinical outcome over a 2–3 year follow-up period, and outcome with regard to social and occupational functioning over the 2–3 year follow-up period. These findings are in agreement with the contention that schizophreniform disorders carry a better prognosis than schizophrenia *per se* (Fox, 1981). However, they do not necessarily support the contention that the two categories of disorder are different entities. If they were, it would surely be expected that there would be some differences with regard to clinical symptomatology (i.e. with regard to the frequency of occurrence of individual symptoms). Also, although the schizophreniform patients did have a better prognosis, they still suffered from a relatively high proportion (over 0.4) of relapses and of occupational, marital, family, and social problems. It is therefore equally possible that the two terms, schizophreniform disorder and schizophrenia, do not describe two different entities, but represent different degrees of acuteness of the same disorder. The apparently better prognosis in the schizophreniform group would then be a reflection of the more acute nature of the illness and the earlier presentation and treatment; both these factors are widely acknowledged as good prognostic indicators in schizophrenics (Slater & Roth, 1969; Bemporad & Pinsher, 1974; World Health Organisation, 1979). Residual schizophrenia, which in the present study carried the worst prognosis and in which duration of illness at index presentation was highest, would then represent the other, more chronic, extreme.

The commonest of Schneider's First Rank Symptoms encountered in both groups of patients with active symptoms was the experience of voices discussing or arguing about the subject, followed by 'made' acts. Other First Rank Symptoms occurred much less commonly. This is in marked contrast to findings from other populations (Mellor, 1970; Carpenter & Strauss, 1974; Chandrasena & Rodrigo, 1979; Bland & Orn, 1980). Unfortunately, the distribution of First Rank Symptoms in Nigerian schizophrenics found in the International Pilot Study of Schizophrenia (IPSS) (see Carpenter & Strauss, 1974) are not available for comparison. The overall frequency of occurrence of First Rank Symptoms in the two groups was comparable to that found in the IPSS.

Follow-up studies in industrialised nations over the current century have confirmed Kraepelin's and Bleuler's original observations that schizophrenia was associated with a poor clinical as well as social prognosis. (The studies are summarised by the World Health Organization (1979).) The international 2–3 year follow-up study carried out by the WHO (World Health Organization, 1979) in five industrialised and four developing countries found that schizophrenia was associated with a better prognosis in terms of clinical outcome in developing countries. The best outcome was recorded from Nigeria. Social outcome, assessed as a single item, was also better in the developing countries. The present study records a much worse outcome – clinically, occupationally, and socially – among schizophrenic patients than found by the WHO study for the developing countries. One reason for this is most certainly the diagnostic criteria employed. Patients were included in the WHO study on the basis of a diagnosis of schizophrenia on ICD-8 criteria (World Health Organization, 1973), which are looser than those of DSM-III, and no minimum duration of illness was employed; indeed, patients whose index illness had been present for more than three years or who had been in hospital for more than two years in the previous five years were excluded from the study. Since 73% of the patients overall (94% of the Nigerian patients) had been ill for less than five months, the great majority would have been given a DSM-III diagnosis of schizophreniform disorder rather than schizophrenia. Indeed, the WHO findings for developing countries, particularly Nigeria, are much more comparable with those of the present study for the schizophreniform group.

The patients described in this paper profoundly illustrate the failure of medical services in Nigeria to deal effectively with the problem of mental disorders. A high level of continued morbidity, both medically and socially, was observed in the majority of cases, even in the so-called better-prognosis 'schizophreniform' group. Clearly, the medical services offered represented merely an interlude, albeit with some temporary relief, in the course of a chronic or recurrent disorder which produces severe disturbances of social and economic functioning. A major problem lies in the fact that psychiatric services in developing countries, with few exceptions, consist of hospital units offering strictly medical services and without the personnel and facilities required for proper rehabilitation and after-care. In reality, patients are being given acute medical treatment of active symptoms, accompanied by rehabilitative measures which consist mainly of counselling of patients and families on the ward. After-care consists essentially of follow-up attendances at the out-patient clinic; the time, expense, and inconvenience to the patient almost invariably results in early failure of patient compliance. The heavy defaulting notable in the present study is therefore not surprising. It is obviously impractical to expect that developing nations can develop the elaborate rehabilitative and after-care facilities found in industrialised nations. However, it should be possible to improve services by developing community-based services manned by less skilled personnel, which would be backed up and supervised by the more highly skilled professionals. This subject is discussed in more detail elsewhere (Makanjuola, 1986). Various such schemes have been advocated but never put into effect. Until they are, the management of schizophrenia (and other mental disorders) in developing countries will continue to be ineffective, and the disorder a source of crippling long-term medical and social morbidity.

Acknowledgements

We acknowledge with thanks the assistance of the members of staff of the Psychiatric Unit, Wesley Guild Hospital, Ilesa and in particular, Mr J. S. Eluyemi, Mrs Awowoyin and Mr Ojo; also the individuals in the various towns who assisted us in our search, in particular, Miss Iyabo Akinola of Esa Oke, Mr Agboola of Oke Imesi, Mr Nduka of Ibadan and Olori Ayeni of Ila Orangun; finally, Miss Olumbunmi Adebisi who typed the manuscript.

The Incidence of Schizophrenia in Nottingham*

J. E. COOPER, D. GOODHEAD, T. CRAIG, M. HARRIS, J. HOWAT and J. KORER

Attempts were made to identify, and include in a two-year follow-up study, every patient living in the catchment area of the Mapperley group of psychiatric hospitals in Nottingham (population 390 000) who made their first-ever contact with the psychiatric services for a potentially schizophrenic illness during a two-year period (1 August 1978 to 31 July 1980). Screening was based upon symptoms rather than diagnosis, covering both in-patient and out-patient services; a consensus diagnosis using ICD–9 was made by the project team. The Nottingham Psychiatric Case Register was used in a retrospective Leakage Study which added nine cases to the 99 identified by the screening procedures. Incidence rates are given for both broad and narrow concepts of schizophrenia, and for DSM–III diagnosis. The Nottingham incidence rates are similar to those reported from other UK centres, and are near the middle of the range found in the other collaborating centres in the WHO study on Determinants of Outcome of Severe Mental Disorders. At entry to the study, 27 patients were out-patients, and 11 were never admitted to hospital at any time in the two-year follow-up period. Reasons for believing that the Nottingham administrative incidence may be close to the incidence in the community are discussed.

The WHO Collaborative Study on Determinants of Outcome of Severe Mental Disorder is an international study between 11 centres, designed and co-ordinated by the Division of Mental Health of the World Health Organization, Geneva.

An important aim of the study is to investigate further some of the findings of its predecessor, the International Pilot Study of Schizophrenia (IPSS) (World Health Organization, 1973, 1975, 1979), in which centres in nine countries took part (Czekoslovakia – Prague; Denmark – Aarhus; Colombia – Cali; India – Agra; Nigeria – Ibadan; Taiwan – Taipei; UK – London; USA – Washington; USSR – Moscow). The two-year follow up of the IPSS patients (Sartorius *et al*, 1977; World Health Organization, 1979) raised the important possibility that schizophrenic patients in developing countries (Nigeria, India, and Colombia) have a better outcome than patients in developed countries (UK, USA, USSR, and Denmark), even though their illness appears to be similar at onset. Other less extensive studies from individual centres have suggested a similar difference in outcome (Rin & Lin, 1962; Murphy & Raman, 1971; Waxler, 1979), but no single study can be regarded as giving definitive findings on this very important possibility. The IPSS, although on a large scale and using standardised methods of assessment and diagnosis (it included a total of 1200 patients, 800 of whom received a diagnosis of some form of schizophrenia), was not designed on an epidemiological basis, and it is possible, although not evident, that varied and unknown selection factors in the different centres were behind the different outcomes.

It was therefore decided to carry out another study using an extended network of collaborating centres, with patients collected in such a way as to obtain in each centre as complete a sample of patients as possible from a geographically defined population. As before, the study is basically a two-year follow-up study, and because of the demonstrated importance in the IPSS of social and demographic influence in determining outcome, steps were also taken to improve the quality and quantity of the information about the personal background, family structure, and social circumstances of the patients.

A joint report on the sociodemographic, clinical and diagnostic description of the study patients in each centre, together with the 'administrative incidence' in each centre, has been prepared by the World Health Organization (1986). The present paper deals with the Nottingham data on incidence rates in more detail, and illustrates how incidence rates may be presented in several different ways.

---

*A report from the UK Field Research Centre of the World Health Organisation Collaborative Study on Determinants of Outcome of Severe Mental Disorders

Specific aims

The aim of the Nottingham study was to identify, and include in a two-year follow-up study, every patient living in the catchment area of the Mapperley group of psychiatric hospitals who made their first-ever contact with the psychiatric services because of a potentially schizophrenic illness during a two-year intake period (1 August 1978 to 31 July 1980).

Method

Method of screening for case-finding

The procedures for screening and assessment were as follows.

A purposely over-inclusive screening schedule (see Appendix 1) was used to identify patients with hallucinations or delusions of any type, or with clearly abnormal behaviour suggestive of psychotic illness, such as social withdrawal, or unexplained severe anxiety, aggression, or excitement. Patients with a clear organic cause for their symptoms, such as brain damage, toxic confusional states, alcoholic psychosis, epilepsy, or severe mental retardation, were not included in the study. All the psychiatric staff covering the psychiatric services of the Mapperley hospital group agreed to apply the screening schedule to all contacts with new patients during the study period. To facilitate this, meetings were arranged with groups of psychiatric staff of all grades of seniority, at which the purpose of the study and the design of the screening process were described. Copies of the screening schedule were deposited in all the out-patient clinics, and they were displayed prominently on the desks at every clinic session; copies were also placed on all in-patient admission wards. All nursing and psychiatric staff were encouraged to contact the project staff if they had the slightest query about a patient's eligibility for inclusion in the study. The instructional sessions were repeated at intervals throughout the study period, particularly after the twice-yearly intake of new junior staff.

Project team members made regular (usually weekly) checks with all the acute admission wards, to see if potential study patients, not already notified, had been admitted.

In addition, Medical Records staff (often doing joint work with the Psychiatric Case Register staff) were asked to notify the project whenever they came across the case-notes of a patient who had made their first contact during the study period.

After the intake period was over, the Mapperley Psychiatric Case Register was used to provide lists of all patients with selected diagnostic categories who had made their first contact during the study intake period. This exercise is described separately later, as part of the 'Leakage Study'.

Method of assessment

Mental state and behaviour

All patients whose screening schedule suggested that they should be in the study were interviewed as soon as possible by a project psychiatrist, who completed the Present State Examination (PSE) (Wing *et al*, 1974). In the great majority of cases, this was done within a few days of completion of the screening schedule; for those patients who were picked up as out-patients or on domiciliary visits, the delay was usually longer (about a week or so).

Psychiatric and Personal History Schedule and social disability

As soon as possible after the PSE schedule had been completed, a different interviewer completed the rest of the schedules with a close relative or other informant, covering the psychiatric, personal, family, and social background (PPHS) and social disability (DAS). In the great majority of cases this was done within one to two weeks. Since one of the issues in the data analysis is the relationship (or lack of relationship) between symptoms and social disability, the PPHS and DAS interviews were always done by an interviewer who had not done the PSE.

Project diagnoses

Project consensus ICD-9 diagnosis. When all the schedules had been completed, the Diagnostic and Prognostic Schedule (DPS) was completed at the next weekly project meeting. At least two (and usually three) project psychiatrists, together with the PHSS and DAS interviewer, discussed all the information available about the patient and family, and also perused the hospital case-notes. A consensus diagnosis was chosen, according to ICD-9, if necessary (but rarely) by a majority vote. Main, subsidiary, and alternative diagnoses were allotted as necessary, as described in the instructions for users of ICD-9 (World Health Organization, 1978). The diagnosis was made using only the information available at entry to the study, which was usually three to four weeks before the team meeting at which the diagnosis was made. In a small proportion of the patients, one or more of the team psychiatrists was also concerned in the clinical care of the patient, and so inevitably was aware of the patient's progress since admission to the study, but this information was not used in making the team consensus diagnosis.

Project diagnosis for certainty of schizophrenia. The presence of main, subsidiary, and alternative diagnoses allows the project diagnosis to be expressed in several different ways. In the presentation of results which follow, it is convenient to use a 'certainty of schizophrenia' code, devised as follows.

1. Schizophrenia certain: the main diagnosis is any of the schizophrenic categories except schizoaffective type (295.0–295.9, except 295.7), and no alternative diagnosis given.
2. Schizophrenia very likely: the main diagnosis is as for 1, but an alternative diagnosis is also given (any code).
3. Schizophrenia probable: the main diagnosis is schizo-affective psychosis (295.7) or a paranoid psychosis (including psychogenic) (i.e. 297.0–297.9, 298.3, 298.4).

4. Schizophrenia possible: the alternative diagnosis is a schizophrenic or paranoid category as in 1–3, but the main diagnosis is not.
5. Not schizophrenia: neither main nor alternative diagnosis is any of the schizophrenic or paranoid categories.

Leakage study

After the study intake period was over, several different types of check were carried out to try to find any cases missed by the screening system just described. These comprised checking with local psychiatrists who engage in private practice; checking with the two private psychiatric hospitals that might have admitted schizophrenic patients from Nottingham during the study period; and checking the records of the Nottingham Psychiatric Case Register.

No previously missed patients were found as a result of checks done by the local psychiatrists who accepted private patients and by the private psychiatric hospitals.

The Nottingham Psychiatric Case Register provided lists of all patients making their first contact with the services in the study period with a hospital diagnosis of Schizophrenia (295), Paranoid States (297), non-affective varieties of Other Organic Psychoses (298.3–298.9), and Paranoid Personality (301.0). The hospital case-notes of all these (*n* = 140) were examined and 13 patients found who had apparently been missed by the screening procedure. Of these 13, two had epilepsy in addition to schizophrenia, one also had an organic syndrome due to alcohol, and in one it was finally decided that the evidence for the presence of hallucinations or delusions was insufficient. This left nine patients who had been legitimate candidates for inclusion in the screening process. The reasons for missing these patients were as follows.

(a) Five patients – seen only as out-patients and never admitted; no special reason apparent why the screening schedule had not been completed.

(b) Two patients – very unwilling patients; seen only once as out-patients by a National Health Service clinician, and refused further appointments offered (with hints of future litigation in one case).

(c) Two patients – brief admissions lasting less than 48 hours, one over a week-end and one over a public holiday.

Sufficient clinical information was present in the case-notes of these nine patients to allow a reasonably confident diagnosis to be made, so a consensus ICD–9 diagnosis was made by two of the project psychiatrists in the same way as for those included in the screening process. Eight of these nine patients had certainty of schizophrenia codes of 1–4, so they were included in the calculation of incidence rates (but not followed up). It is worth noting that only three of the nine cases from the Leakage Study fall into the 'certain' or 'very likely' codes for schizophrenia already described, so their addition makes very little difference to the incidence rates of the more definitely schizophrenic diagnoses.

Results

Number of patients and rate of intake to the screening procedure

A total of 99 patients were taken into the study by means of the above screening procedure, 53 in the first year of intake and 46 in the second. The rate at which the patients entered the study was fairly steady, averaging out over the two years at just under one patient per week. In most months, between two and five patients were found, with few extremes (one month with ten cases and two months with one case); the range of 2–5 cases per month covers more than half of the months of the study. This group of

99 patients is referred to as the Total Screening Intake group. The Diagnostic Certainty of Schizophrenia is shown in Table I for the 99 patients in the Total Screening Intake group, plus the nine patients found in the Leakage Study (total $n = 108$).

The screening schedule was designed on a symptomatic basis as already noted, so as to produce a somewhat over-inclusive group from the diagnostic point of view. This is evident in that for ten of the 99 patients, all their main, alternative and subsidiary diagnoses were in the affective, neurotic or adjustment reaction categories; nine of these ten had a main diagnosis of Mania or Depression with mood-congruent delusions or hallucinations. The rates that are discussed below for the diagnosis of schizophrenia at various grades of confidence do not include these ten patients. The remaining patients were divided up in several ways for calculation of the incidence rates that follow, according to the narrowness or breadth of the diagnostic concept of schizophrenia that is under discussion.

The monthly variations in the rate of intake to the study of the total of 97 potentially schizophrenic patients (certain = 37 + 2 leakage; very likely = 30 + 1 leakage; probable = 11 + 4 leakage; possible = 11 + 1 leakage:total = 97) were not significant. The rate of intake to the study is only of administrative interest, and does not necessarily have a direct relationship to the time or type of onset of the illness. These aspects will be described in detail in later reports, but it is of interest to note that one-third of the patients had an illness onset that could be clearly identified in the four weeks preceding admission to the study.

Incidence of schizophrenia

Several different incidence rates for schizophrenia can be derived, depending upon different definitions of schizophrenia. The joint report from all the field research centres in this study (World Health Organisation, 1986) uses the CATEGO data derived from the PSE ratings. This is the most standardised type of diagnostic statement available, and is appropriate for comparisons between centres even though it does not have quite the same meaning as a set of clinical diagnoses expressed in terms of ICD-9. The CATEGO data will not be discussed here again in detail, apart from a brief mention in the discussion section. The rates given here are based upon the project ICD-9 consensus diagnosis, which probably bears a close resemblance to diagnoses made by many general psychiatrists in the UK. Rates are given for both broad and narrow definitions of schizophrenia using ICD-9, and for schizophrenia using DSM-III.

Using a broad definition of schizophrenia

The top section of Table II shows the age- and sex-specific rates for the summed ICD-9 categories of

(a) all categories of Schizophrenia (295)
(b) Paranoid States (297)
(c) non-affective types of 'Other Non-Organic Psychosis' (298.2–298.9) (often called 'Reactive Psychoses').

There are 85 patients in this group, which will be referred to as the Total Incidence of Schizophrenia group. It is derived from the Total Screening Intake group ($n = 99$) by taking out those patients with a main diagnosis in the Affective Psychosis or non-psychotic categories ($n = 10$) and then adding the seven patients from the Leakage Study with schizophrenic-related main diagnosis. (This is the same as adding together the first three 'certainty of schizophrenia' groups, of certain, very likely and probably schizophrenia, and seven patients from the Leakage Study.) The rates are markedly higher for young men than for young women, with a less marked reversal of this difference in the 40–49 age group. For men and women together, the rates are highest (2.8 per 10 000) in the 20–29 year age group.

For the ICD-9 definition of Schizophrenia (295.0–295.9)

The middle section of Table II shows the rates for men and women together derived from the 76 patients (52 men and

TABLE II

Mean annual incidence of new cases of schizophrenia: Nottingham (August 1978 to July 1980)

	Rates per 10 000 (numbers in brackets)					
	Age 15–19	*Age 20–29*	*Age 30–39*	*Age 40–49*	*Age 50–54*	*All ages 15–54*
ICD-9 broad concept of schizophrenia[1]						
Male	2.1 (7)	4.0 (27)	2.6 (13)	1.4 (6)	1.4 (3)	2.8 (56)

DSM-III Schizophrenic Disorder						
Male and female	0.3 (2)	1.4 (16)[3]	1.1 (10)	0.7 (6)	0 (0)	0.8 (34)[4]

1. 295, + 297, + 298.2–298.9.
2. Male 26, female 3.
3. Male 16, female 0.
4. Male 23, female 11.

24 women) with ICD-9 Schizophrenia (295) as a main diagnosis. The same differential pattern for age and sex exists as for the broad definition.

An even narrower definition of schizophrenia can be achieved by omitting the six patients with a main diagnosis of Schizoaffective Schizophrenia (295.7), but this makes little difference to the overall rates, and does not affect the sex and age differences.

Incidence rates using DSM-III

A DSM-III diagnosis (American Psychiatric Asociation, 1980) was also made for all the patients in the study. This was not done at the time of entry, since the final form of DSM-III was not then available. Some time after the study was completed, two psychiatrists, one of whom (JEC) was familiar with the study and the patients, made themselves familiar with DSM-III, and then made independent diagnoses on all the study patients on DSM-III (Gregory & Cooper, 1983). All the special study documents (schedules and narrative summaries) and the hospital case-notes were used. An agreed DSM-III diagnosis was then reached by discussion of any differences in the independent diagnoses.

Because of the DSM-III requirement of the presence of symptoms for at least six months to qualify for a diagnosis of Schizophrenic Disorder, only 34 patients received this diagnosis. The incidence rates derived from these patients are shown in the bottom section of Table II. At entry to the study, the 76 patients with an ICD-9 diagnosis of Schizophrenia (295) were divided between the DSM-III diagnoses of Schizophrenic Disorder ($n=34$), Schizophreniform Disorder ($n=20$), Schizoaffective Disorder ($n=4$) and Atypical Psychosis ($n=18$). Some of these patients fulfilled the six months duration of symptoms criterion during the follow-up period, so it is possible to derive a compound 'retrospective incidence' rate for DSM-III Schizophrenic Disorder by adding together the 34 patients qualifying at entry and those qualifying later (ten men and five women). This gives an overall age-specific rate of 1.7 per 10 000 for men ($n=34$) and 0.7 per 10 000 for women ($n=15$), and an overall rate for men and women together of 1.3 per 10 000 ($n=49$).

Rates per total population

All the rates quoted above are age- and sex-specific. Since new cases of schizophrenia are rare below the age of 15 and above the age of 54, and there are marked sex differences at some ages, age- and sex-specific rates give a more complete picture of the incidence of schizophrenia than total population rates. But some studies quote only total population rates, so these are needed in order to make comparisons. For Nottingham, this means that the population base rises from 202 214 aged 15-54 years to 380 028 total population of all ages. The rates therefore fall to just over half of the age- and sex-specific rates; the overall rate (men plus women) for the broad ICD-9 concept falls from 2.2 to 1.2 per 10 000, the ICD-9 Schizophrenia (295 only) falls from 2.0 to 1.1 per 10 000, and the DSM-III rate for Schizophrenic Disorder at entry falls from 0.8 to 0.5 per 10 000 (the DSM-III compound retrospective incidence rates for men and women together falls from 1.3 to 0.7 per 10 000).

Discussion

Administrative incidence and the completeness of the sample

The effort put into obtaining as complete a sample as possible for this study was aimed primarily at providing the best possible group for follow-up, rather than being able to quote very accurate incidence rates. Nevertheless, the comparison of the Nottingham incidence rates with those found in other similar studies is of considerable interest, since it is likely that the Nottingham sample is close to being complete.

As the joint paper (World Health Organization, 1986) emphasises, the aim in this study is to estimate the 'administrative incidence'; that is, to obtain a complete sample of patients making their first-ever contact with those services or agencies which were identified in each centre as usually being the most important early point of contact for an individual with severe mental illness; in the UK this was taken to be contact with a psychiatrist. The study does not have the more ambitious aim of estimating the total community incidence. In some of the study centres it is difficult to estimate precisely how big the difference between administrative incidence and community incidence might be, although detailed study of this point often suggests that the difference may be surprisingly small. In the UK, and in Nottingham in particular, there are a number of reasons for believing that the administrative incidence and the incidence in the total community may be very similar. The Nottingham rates can also be regarded as those of a typical English urban community, as far as such a concept is useful. The reasons stem from the nature of the Nottingham community, the structure of the UK National Health Service, the particular structure within this of the psychiatric services of the Mapperley group of hospitals, and the presence of a psychiatric case register.

The nature of the Nottingham community

The town of Nottingham has a comparatively stable population with little outward movement, and the population indices for such items as social class and type of housing are close to the national average. The proportion of the population born overseas or of recent overseas origin is stable at around 7%.

The structure of the UK National Health Service

Virtually everybody in the UK is registered with a general practitioner in the National Health Service, to whom referral is quick, easy, and free. It is very unusual in the UK for general practitioners not to refer patients to the psychiatric services if they suspect a serious mental illness. This was confirmed by one of the authors (JEC) when making personal contact with over 20 general practitioners (for the purposes of another study) during the intake period. When asked if they ever treated patients who might possibly have schizophrenic or other serious mental illness without requesting a specialist opinion as soon as possible, without exception the general practitioners reported that they always sought psychiatric advice without delay.

There is very little private psychiatric practice (i.e. outside the National Health Service) in Nottingham. At the time of the study, only two of the 12 consultants covering the catchment area accepted private patients, and then only for a maximum of one-tenth of their working week. In any case, patients with serious and potentially chronic illness will almost always be treated within the National Health Service after the first consultation. As noted, checks on the local private practitioners were included in the Leakage Study.

The structure of the psychiatric services of the Mapperley group of psychiatric hospitals

The psychiatric services centred upon Mapperley Hospital cover the majority (390 000) of the population of the town of Nottingham (population about 400 000, depending upon how it is defined). The hospital catchment area is defined exactly, and no other psychiatric services operate within the area. In-patient, day-patient and out-patient services (including domiciliary visits) were all covered by the Mapperley-based psychiatrists, working in sector-orientated clinical teams. At the time of the study, there was an increasing emphasis on sectorisation, and on community-based care and close collaboration with general practitioners. It is very unusual, as subsequent checks in the Leakage Study showed, for patients of any sort to be referred to psychiatrists outside the hospital catchment area.

Nottingham in relation to the other field research centres in the WHO study

Nottingham is around the middle of the range of rates found in the eight field research centres for which incidence rates can be calculated with confidence (Aarhus, Chandigarh - urban, Chandigarh - rural, Dublin, Honolulu, Moscow, Nagasaki, and Nottingham). These rates and other incidence data are presented in more detail in the joint report (World Health Organization, 1986). It is sufficient for present purposes to note that, for instance, of the 85 Nottingham patients in the 'broad definition of schizophrenia' group, 66% have a CATEGO class of S^+ (this class indicates the presence of one or more 'first rank' symptoms (Schneider, 1959, 1974; Mellor, 1970)). A further 16% have CATEGO classes of S?, P^+ or O^+, so a total of 82% of Nottingham patients have CATEGO classes known to be very strongly correlated with a clinical diagnosis of schizophrenia. This proportion puts Nottingham into fourth place among the above eight centres.

The separate age- and sex-specific rates are shown in Table II only for the largest group (the broad definition of schizophrenia), since the numbers in the smaller age- and sex-specific groups become very small when the total in the group drops. However, in spite of the small numbers, the pattern of sex and age distribution seen in the broad definition group is maintained throughout; that is, markedly more young men than young women, and slightly more women aged 40–49 than men. The same pattern is also found in 10 of the 12 centres in the overall WHO report, so this pattern, although not an invariable finding in previous studies, is common enough to be regarded as fairly typical.

Comparisons with other incidence studies, and the accuracy of case register information

The Nottingham total population rates derived from this study are lower than those from the Salford Case Register, and the same as those from Camberwell; for 1969–1973, the Salford and Camberwell mean rates were 1.4 and 1.1 per 10 000 respectively (Wing & Fryers, 1976). The uncorrected Nottingham Psychiatric Case Register rate (for the total population) is the same as for the Salford Psychiatric Case Register.

Comparison with rates from other studies done in other countries is of interest, but there is no point in going into great detail since these previous studies were done under different (usually more difficult) service conditions, with different diagnostic criteria and with less standardised methods of assessment and diagnosis. When reviewing these problems in relation to incidence rates, Cooper (1978) noted rates of 7.2 per 10 000 in New York State (Babigian, 1975), 5.4 in Mannheim (Hafner & Reimann, 1970) and 5.2 in Dublin (Walsh, 1969). He predicted correctly that "more rigorous definitions of a new case might result in much reduced estimates", and it seems likely that the Nottingham, Camberwell, and Salford case register rates, all of the same order of magnitude and markedly lower than most other rates quoted in the literature, represent the effect of efforts in this direction. A more recent report from Ireland (O'Hare *et al*, 1984) also seems to fulfil this expectation.

Incidence rates using DSM–III criteria

No other DSM–III figures are yet available for comparison. The DSM–III requirement that symptoms must have a duration of at least six months before the patient can qualify for 'Schizophrenic Disorder' raises a new type of problem in psychiatric epidemiology. Even the complex 'retrospective incidence rate' reaches only 0.7 per 10 000 total population, and all the age- and sex-specific rates on DSM–III criteria are much lower. Whether or not it is justified to include a criterion of long duration of symptoms in the definition of schizophrenia, or any other disorder, needs to be debated elsewhere, but the effect on incidence rates is immediately clear. An incidence rate no longer has the same meaning as for other disorders that do not possess a criterion of long duration, and unless a survey of such a disorder continues as a follow-up study for at least as long as the specified duration of symptoms, the determination of incidence rate cannot be complete.

Effects of ICD–9 criteria and the service setting of this study

In contrast to the DSM–III criteria, the ICD–9 description of schizophrenia contains no restrictions on duration of symptoms: schizophrenia can range from very acute to chronic, and the symptoms need to last only long enough to bring the patient to the attention of those making the assessment.

Particular care was taken to follow the ICD–9 description for all the schizophrenic and paranoid categories, so the diagnoses arrived at represent the cross-sectional descriptive approach that is typical of most parts of ICD–9.

A number of the Nottingham patients have illnesses of very acute and recent onset, with clear possible causes; it is very likely that some psychiatrists would be reluctant to make a diagnosis of schizophrenia in such patients and would prefer labels which, in their particular view, carry different implications about aetiology and prognosis.

If this point is taken together with the likelihood that very few patients from the catchment area population have been missed, it can be concluded that this group of patients is an unusually complete sample of those suffering from psychiatric illnesses that can be called schizophrenia quite legitimately according to the cross-sectional descriptive approach used in ICD–9. Both acute and less acute disorders are included, with and without clear aetiology, and irrespective of their service status after being identified. For instance, 27 patients were out-patients at entry to the study, and 11 were never admitted to hospital at any time in the two years of the follow-up. This study group is therefore suitable for investigating the implications of the ICD–9 concept of schizophrenia and related illnesses, in both cross-sectional and longitudinal studies. Much effort was put into the collection of information about the social background, family composition, and social disabilities of these patients, and the main interest of the study lies in the relationship during the follow-up period of these additional types of information with the clinical state.

Acknowledgements

We are most grateful to the consultant staff of the Mapperley group of hospitals for permission to study their patients. Medical, clerical and administrative staff gave considerable help in finding and contacting the patients during the period of study, for which thanks are due. The study was supported in part by grants from the Division of Mental Health, World Health Organisation, Geneva, and from the Department of Health and Social Security.

Appendix 1
Extract of main points covered by the screening schedule

Section A. Temporary residents, visitors and persons of no fixed abode were included only if they had lived in the catchment area for at least six months in the year preceding the contact.

Section B. Exclusion criteria (any of 1–3):
1. Clinically manifest organic cerebral disorder (confusion etc.)
2. Severe or moderate mental retardation
3. Organic CNS damage (encephalopathy).

Section C. Inclusion criteria (any of 1–5):
1. Hallucinations or pseudo-hallucinations in any modality
2. Delusions
3. Marked thought and speech disorder
4. Marked psychomotor disorder
5. Emergence of marked exacerbation of bizarre and grossly inappropriate behaviour.

Section D. Inclusion criteria – a definite change of personality and behaviour during the last year, manifested in any of the following:
1. Marked reduction or loss of interests, initiative and drive
2. Emergence or marked exacerbation of social withdrawal
3. Severe excitement, purposeless destructiveness or aggression
4. Episodic or persistent states of overwhelming fear or severe anxiety
5. Gross and persistent self-neglect.

Section E. Exclusion criteria: admission to hospital, or diagnosed or treated for a psychotic disorder similar to or continuous with the present illness, at any time before the last three months.

Ecological Structure and the Distribution of Schizophrenia and Affective Psychoses in Nottingham*

J. A. GIGGS and J. E. COOPER

The 800 census enumeration districts of Nottingham were used as a basis for the production of 12 distinct 'clusters' or neighbourhood types. Plotting the place of residence of the 68 patients with 'certain' or 'very likely' diagnoses of ICD-9 schizophrenia, identified in the World Health Organization Study of Determinants of Outcome of Severe Mental Disorders, showed the expected concentration in central areas of low social status. A more varied distribution was found for 132 patients with a case-register diagnosis of affective psychosis, contacting the psychiatric services for the first time during the same two-year period as the schizophrenic patients. Some of the highest rates for affective psychosis were found in new housing estates of middle and low status at some distance from the town centre.

The study of the geographical distribution of psychiatric disorders in urban populations has a quite substantial pedigree. It is generally accepted that Faris & Dunham (1939) established the methodological foundations of modern ecological psychiatric investigations, for in addition to providing a comprehensive review of then existing research, they also showed that, within Chicago, there were substantial spatial variations in both the incidence and prevalence rates of psychiatric hospital admissions. For every diagnostic group except manic-depression, the highest rates were found in the populations living in central city neighbourhoods. With increasing distance from the inner city the rates declined regularly and progressively, in a broadly gradient-like fashion. The methodology of this pioneer study has since been repeated frequently in many countries (Freeman, 1984). In almost every case the geographical patterns identified have been substantially the same as those revealed for Chicago.

Although the techniques employed in all these studies have been essentially geographical, it is a regrettable fact that geographers themselves have contributed only modestly, and recently, to this important field (Giggs, 1973, 1980, 1983; Smith, 1980, 1984). However, despite the relative novelty of their involvement, geographers have been able to demonstrate that the analysis of spatial variations in the distribution of mental disorders within cities is characterised by both serious problems and considerable potential. These issues are discussed in detail elsewhere (Giggs, 1979, 1983; Smith, 1980, 1984). A report on the incidence of schizophrenia in Nottingham (Cooper *et al*, 1987) provides the opportunity to exemplify some of the specifically geographical contributions to the analysis of the spatial distribution of this severe mental disorder.

In attempting to identify variations in the geographical distribution of mental disorders within large urban areas, the researcher is faced with a seemingly bewildering array of choices concerning which particular set of sub-areas to choose. Thus for Chicago, Faris & Dunham (1939) used several spatial frameworks for their maps, ranging from 120 'subcommunities' (i.e. blocks of neighbouring census tracts) at one end of the scale, down to only 11 'natural area' types, differentiated by contrasting social and housing attributes. In contrast, most British researchers have used electoral wards. A recent analysis of psychiatric hospital admissions in Bristol (Ineichen *et al*, 1984) typifies this strategy. Regrettably, however, electoral wards are too gross, since they generally contain markedly divergent social and housing attributes. Their boundaries rarely coincide with those of the social and housing areas found within cities. Moreover, from the 1966 population census onwards, in Britain, it has been possible to obtain census data for the so-called 'small areas' (i.e. enumeration districts, with an average population size of 500 persons). Using well-tested statistical methods (Knox, 1982; Davies, 1984), geographers have shown that these small areas can

---

*A report from the UK Field Research Centre of the World Health Organisation Collaborative Study on Determinates of Outcome of Severe Mental Disorders

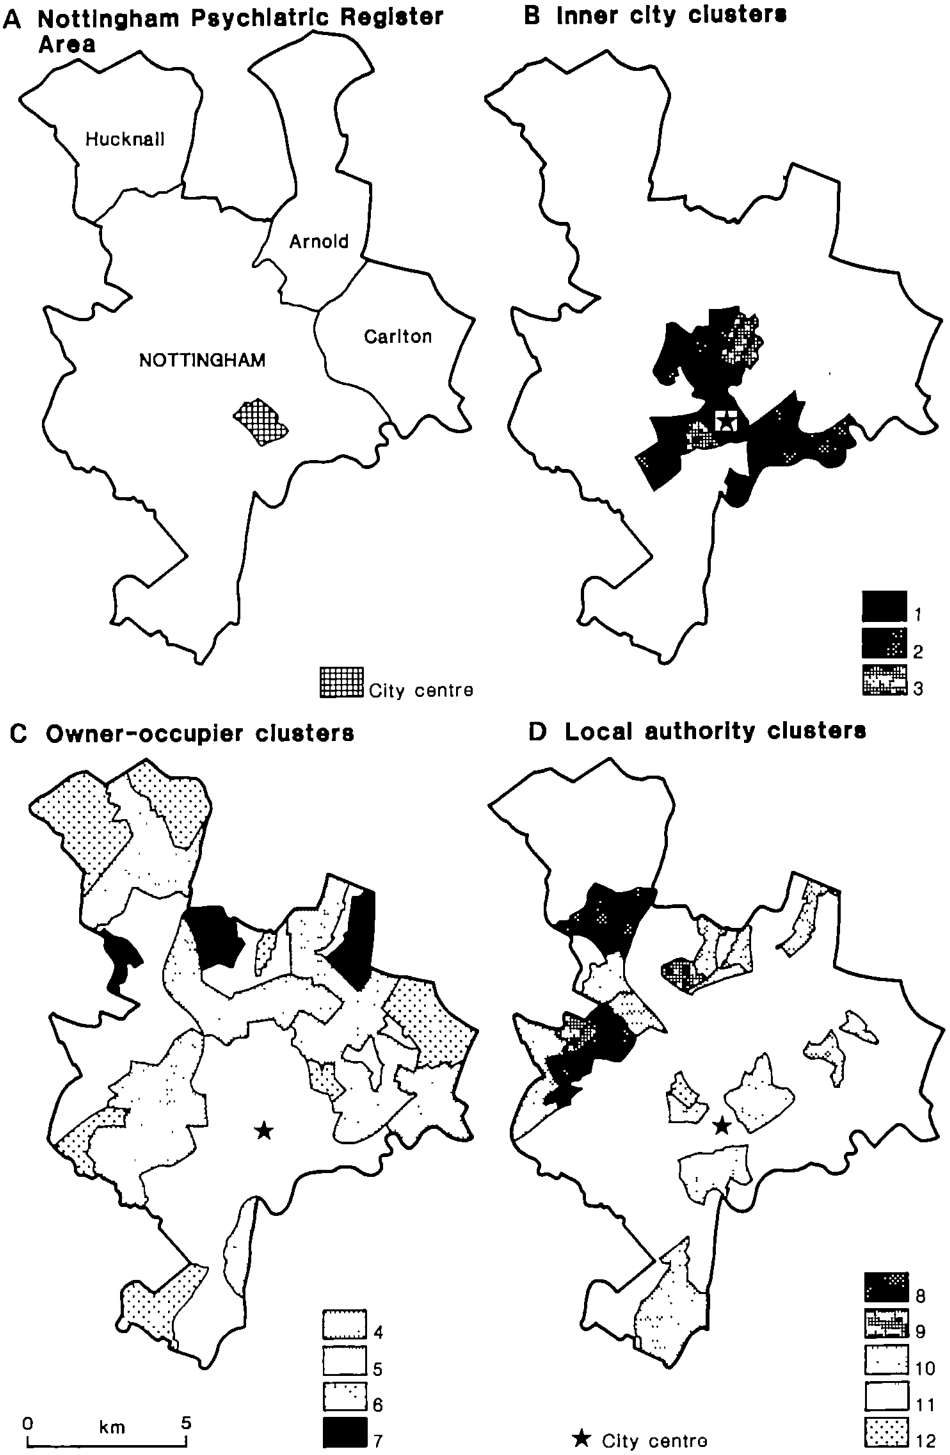

FIG. 1 Nottingham Psychiatric Register area and its neighbourhoods.

be grouped into larger units possessing uniform social and housing characteristics. Thus the analysis by Short (1978) of ten social and housing variables in Bristol identified eight neighbourhood types which would provide a contextual framework superior to electoral wards for the analysis of the geographical distribution of mental disorders.

Method

For the present investigation, 36 of the 1981 census variables and four variables derived from local authority sources (Payne, 1983, 1984) were collected for the 800 enumeration districts located within the Nottingham area. This data matrix was then analysed using Principal Components Analysis and a clustering program (Giggs & Cooper, 1986). These methods revealed that Nottingham is characterised by 12 distinct 'clusters', or neighbourhood types (Fig. 1, parts B–D). Some of the major social and housing attributes of these neighbourhoods are presented in Table I. It is suggested that these statistically derived areas provide an effective contextual framework for the analysis of spatial variations in the incidence of mental disorders. The computer-based data bank of the Nottingham Psychiatric Case Register has recently been matched with an address-based computer file (Giggs, 1984*a*). Consequently it is now possible to code the place of residence of every patient (from 1975 onwards) by enumeration district, and then to map the distributions. This has been done for both the 68 schizophrenics and the 132 patients with affective psychosis. At the time of the study, the Nottingham Psychiatric Case Register recorded all face-to-face contacts between psychiatrists and psychiatric patients living in the catchment area of the psychiatric services based on the Mapperley group of hospitals (population 380 000). This catchment area (defined exactly, street by street) contained the great majority of the town of Nottingham, and so was virtually all composed of inner-city, urban or suburban environments. Because of the nature of the National Health Service, the structure of the Nottingham psychiatric services, and the absence of alternative types of psychiatric care, there are good reasons to presume that the 'administrative incidence' of schizophrenia and other serious mental illnesses in Nottingham (Cooper *et al*, 1987) is close to the incidence in the community as a whole, particularly for schizophrenia.

The schizophrenic patients examined here comprise the 68 who were given study diagnoses of 'certain' or 'very likely' schizophrenia in the latest World Health Organization collaborative study (Cooper *et al*, 1987). At the time of first contact these patients were living in private households (i.e. in non-institutional settings) within the Nottingham Case Register Area (part A of Fig. 1). In addition, for comparative purposes, the analysis includes a consideration of the 132 patients with a hospital diagnosis of ICD-9 296.0–296.6 (i.e. the more specific forms of affective psychosis) who contacted the local psychiatric services for the first time during the same two years as the schizophrenic group (August 1978 to July 1980). These patients were obtained retrospectively from the Mapperley Psychiatric Case Register, so their diagnoses were not derived from the same consensus method as the diagnoses of the schizophrenic patients. However, the way in which the hospital psychiatrists are known to use the diagnoses of affective or manic-depressive psychoses means that it can be said with confidence that the group is composed almost entirely of patients with severe depression or obvious hypomania. This was also confirmed when the case-notes of these patients were examined during the 'Leakage Study' to ensure that there were no schizophrenic patients among them (Cooper *et al*, 1987).

Results

The average annual incidence rates of both schizophrenia and affective psychosis for the 12 neighbourhood types are presented in Table II, together with the standardised rates (i.e. the rate for each neighbourhood type expressed as a ratio of the rate for the whole of Nottingham). The standardised rates for schizophrenia and affective psychosis are also mapped in parts A and B of Fig. 2. It is evident that there are substantial spatial variations in the incidence of these two severe mental disorders. In the case of schizophrenia the pattern is the familiar one of inner city dominance (Fig. 2, part A), with rates exceeding twice the Nottingham average. For affective psychosis, however, the distribution pattern is strikingly different. Thus the highest rates are found in certain suburban areas, namely the cluster 7 tracts (compare Fig. 1, part C and Fig. 2, part B). These are typified by middle status, early to mature families (i.e. children, parents under 45 years old), high population turnover, and post-1970-built owner-occupied housing. Above-average rates are also found in several inner city neighbourhoods. This more varied distribution pattern has also been found in many other large urban areas (Faris & Dunham, 1939; Hare, 1956; Levy & Rowitz 1973; Bagley & Jacobson, 1976), but the comparatively high social status of the tracts with the highest rates of affective psychosis is a new finding.

Although many researchers have demonstrated that there are substantial variations in the distribution of various mental disorders within cities, few have subsequently tested the *significance* of these findings. In the few instances where statistical tests *have* been used, the spatial units employed have been highly aggregated (e.g. Gerard & Houston, 1953; Jaco, 1954; Hare, 1956). Thus Hare (1956) grouped the electoral wards of Bristol into only three units. The dearth of statistical tests in the literature of psychiatric ecology is a serious issue, because the testing of results is an important stage in epidemiological research. Cooper (1973) has argued that "The basic aims of epidemiology are to estimate rates of (disease) inception and prevalence in populations, *and to test for differences between the rates for defined subgroups*".

The distributions of schizophrenia and affective psychosis in Nottingham were therefore analysed, using the Poisson

probability test (Norcliffe, 1977). It is thus possible to determine whether the incidence of the two disorders is significantly higher or lower in any of the 12 neighbourhood types than in the population of the entire study area. The results of these tests are shown in parts C and D of Fig. 2. The analyses confirm that the inner city neighbourhoods of Nottingham have significant excesses of schizophrenics (Fig. 2, part C). In contrast, the significant excesses of affective psychotics are found chiefly in three middle-status suburban tracts ($P<0.01$), but also in the central, low-status, 'rooming house' district (i.e. neighbourhood type 1, $P<0.05$; compare Fig. 1, part B and Fig. 2, part D).

Discussion

The distribution of new schizophrenic patients in Nottingham during the late 1970s was very similar to that in Chicago some 50 years ago (Faris & Dunham, 1939). However, there are some important differences between the findings for Nottingham and those of Chicago and other cities. The Nottingham study has a more complete sample of the total possible cohort of schizophrenics in the community (11 of our patients were never admitted to hospital), and the information on the Nottingham patients and, in particular, the project diagnosis, was of a higher quality and reliability. In contrast, the Chicago study and virtually all subsequent investigations were based exclusively on hospital admissions and the collected hospital admission diagnosis, whose quality must have been difficult to assess.

The Nottingham study also differs from previous studies because the spatial distribution of schizophrenia has been analysed and tested within the context of an objectively derived set of distinctive neighbourhoods. These areas provide a more accurate characterisation of the significant social and housing areas of cities than the large administratively defined areas (e.g. electoral wards) which customarily have been used in intra-urban ecological studies.

Despite these important differences, the essential similarity of the findings of the present study and existing research is marked. The apparent stability of the intra-urban spatial distribution of the incidence of schizophrenia across both time and nationality is striking. Two earlier investigations of the incidence of schizophrenia within Nottingham confirm the marked stability of the high-rate inner city neighbourhoods over nearly two decades (Giggs, 1973, 1983). This local stability is also striking. Between 1971 and 1981 the total population of the whole of Nottingham remained fairly stable, declining by only 5.6%. However, this general picture conceals highly divergent local variations within the study area. Thus the four working class inner city neighbourhoods (i.e. groups 1, 2, 11 and 12 – see Table I and parts B and D of Fig. 1) experienced population losses of between 28.0% and 44.7%. Moreover, these are not population losses overall: between 1961 and 1971 the nineteenth century slum housing in the tracts comprising neighbourhoods 11 and 12 was completely demolished and replaced by new inner city local authority housing estates and deck-access flattened complexes. During the decade, the former residents were rehoused in suburban estates and very few subsequently returned to the renewed inner city housing areas. Despite these profound changes in the size and character of the population and the housing stock between 1971 and 1981, the incidence of schizophrenia during 1978–1980 was remarkably similar to that during 1969–1973 (Giggs, 1983) (but it must be noted that the 1969–1973 rates were based upon uncorrected case-register diagnoses).

For the diagnosis of affective psychosis, the geographical distribution is very different from that for schizophrenia. Instead of a single major central city concentration of high rates, there is an apparently random scatter (Fig. 2, parts B and D), but a separate investigation of the ecological correlates of this disorder (Giggs & Cooper, 1986) suggests that the high rates of manic-depressive psychosis are correlated with high levels of population mobility. Thus the highest rates of this particular psychosis are concentrated in the new suburban estates (i.e. neighbourhood 7) and the inner city 'rooming house' district (i.e. neighbourhood 1), both of which are known to be characterised by high population turnover. Similar findings have been reported elsewhere (Giggs, 1984*b*).

The distribution of schizophrenic patients that we have found is broadly what we expected, but there are two main points of special interest. Firstly, the findings are unusually clear-cut, probably because of the unusually precise and comprehensive characterisation of both the schizophrenic cohort and the neighbourhoods within Nottingham. Secondly, we shall be exploring the connections between place of residence (i.e. neighbourhood type and characteristics) and follow-up. We shall be analysing the extensive information that we have on clinical state and social disability at the one-year, two-year and later follow-up points. Some interesting findings concerning residential mobility behaviour have already been identified (Giggs & Cooper, 1986).

The geographical data, like that on incidence rates, is of interest in its own right, but it has greater practical importance when set against outcome. The main purpose of this collaborative study is to try to learn more about what determines outcome in schizophrenia. To do this we need to examine carefully and systematically as many attributes of the patients, their families, and their neighbourhood settings as we can.

No particular aetiological clues connected with these different geographical distributions emerge from the data of this study at the present state of analysis. Limitations of manpower and finance made it impossible to carry out formal studies of pre-morbid life events, which could perhaps be associated with the different styles of life in the ecologically different areas. Looking at the possibility using information collected at the ordinary clinical level of detail and accuracy, there was no particular suggestion of unusually high rates of stressful events or physical illnesses. The new finding of high rates of manic-depressive illness in areas of high population mobility and a reasonable level of material resources suggests that it would be justified to study the pre-morbid personality and social mobility of this type of patient and family.

Acknowledgements

The authors gratefully acknowledge that this research was funded by research grants from the Economic and Social Research Council, and from the Department of Health and Social Security. We are also grateful to Dr John Howat and the staff of the Mapperley Psychiatric Case Register who were involved in the establishment of the linkage between the case register and the census data.

Double-Blind Comparison of Half-Dose and Standard-Dose Flupenthixol Decanoate in the Maintenance Treatment of Stabilised Out-Patients with Schizophrenia

D. A. W. JOHNSON, J. M. LUDLOW, K. STREET and R. D. W. TAYLOR

A double-blind controlled trial of 50% dose reduction in maintenance treatment in stable out-patients with low BPRS scores and good social function shows a significantly higher relapse rate in the low-dose group at 12 months ($P<0.05$). After an interval of 24–36 months from dose reduction, 56–76% had experienced a relapse and 76–79% had resumed their former dosage. No clear advantage was shown for the lower dose in either a reduction of side-effects or improved social function, but a reduced prevalence or lower rate of symptom emergence for tardive dyskinesia was suggested.

The value of long-term maintenance neuroleptic treatment in preventing psychotic relapse has been well demonstrated (Leff & Wing, 1971; Hogarty *et al*, 1973, 1974, 1976; Hirsch *et al*, 1973; Davis, 1975; Rifkin *et al*, 1977; Johnson, 1979, 1984; Schooler *et al*, 1980; Kane *et al*, 1982; Johnson *et al*, 1983), with the knowledge that responders should continue on regular medication for an unknown period in excess of 5 years. The longer-term experience with these drugs has made us more cautious, since they have the potential to produce unwanted side-effects such as extrapyramidal symptoms, tardive dyskinesia, weight gain, and akinesia. In all these unwanted effects, either the current dose or the total dose over time has been found to be a dependent variable. It is essential, therefore, to establish the lowest dose possible for the successful maintenance of patients, although the range is likely to be substantial, since no single dose will be correct for all patients.

Reviews of the actual regimens prescribed in controlled trials have led to the conclusion on theoretical grounds that much lower doses than commonly used might be equally effective (Baldessarini & Davis, 1980; Teicher & Baldessarini, 1985). In those controlled trials that permitted estimates of the equivalent dose of chlorpromazine to be plotted against reduction of relapse, no significant dosage effect in the range 100–2000 mg/day was found, and no mean difference in outcome at dosages above compared with dosages below 310 mg/day. It has also been demonstrated that some chronic patients can be successfully maintained on very small doses, relapsing when their drug is discontinued (Capstick, 1980).

In a trial of only 10% of the existing dose prescription of fluphenazine decanoate, Kane *et al* (1983) compared a low-dose group (1.25–5.0 mg per 2 weeks) with a standard-dose group (12.5–50.0 mg per 2 weeks) over 12 months, the subjects being out-patients. The relapse rate was significantly higher in the low-dose group (56% *v*. 7%). Kane (1984) subsequently studied a group of patients on 20% of the standard dose and reported a reduced relapse rate of 20% over 12 months. Marder *et al* (1984) reported a double-blind comparison of two groups of out-patients – a low-dose group on 20% of the previous dose, and a standard-dose group (5 mg *v*. 25 mg fluphenazine decanoate per 2 weeks). At the end of 12 months, the two doses appeared to be having equal effect. During the second year, the low-dose group became significantly disadvantaged, with a wide separation of the survival curves after 15 months. The standard-dose group had a negligible relapse rate in the second year, while the low-dose group had a fairly constant relapse rate throughout both years (31% *v*. 64% at 24 months). The apparent equal outcome at 12 months may be an artefact of the entry procedure into the trial, since most relapses in the standard-dose group occurred within the first 3 months. It is likely that some early relapses occurred before stabilisation on the standard-dose therapy had been established.

The low-dose studies all suggest that if relapse is the sole criterion of assessment, then standard-dose therapy is superior. However, suggestions have been made that the risks of side-effects may be less and the comfort and function of the patient improved by use of low doses. It has also been suggested that any relapse as a consequence of a reduced dose may have a less dramatic onset than relapse following complete withdrawal of medication, so remedial therapy may be offered. These practical advantages have not yet been established.

So far, there have been no studies investigating a dose reduction of less than 80%, nor any using the depot injection flupenthixol decanoate. The present study compares half dose and standard dose flupenthixol decanoate maintenance therapy over 12 months, and reports the 2–3 year outcomes of reduced medication.

Method

The sample was of consecutive out-patients who had been diagnosed as suffering from schizophrenia by their psychiatrist and who met the Feighner criteria (Feighner *et al*, 1972). All patients were on the normal treatment regimens used by their psychiatrist. In addition, they had to score no more than 3 on the total score of the Brief Psychiatric Rating Scale (BPRS) (Overall & Gorham, 1962), to have been maintained on a relatively low dose of flupenthixol decanoate over the last 12 months, and to have been on a stable dose of no more than 40 mg every two weeks for the past 6 months (in practice all patients had been on this stable dose for 12 months or longer before commencement of the trial). No patient was accepted with organic brain disease, physical illness, alcohol or substance abuse, below normal IQ, or additional mental illness. All patients had to give informed consent. Any patient might be withdrawn at his own request or at the discretion of the psychiatrist.

Patients fulfilling these criteria were allocated to one of two patient groups on the basis of a sealed computer randomisation. Group A continued on their pre-trial dosage for 12 months and then had their dose reduced to half. Group B had their pre-trial dosage reduced to half at the onset.

For both groups follow-up continued for three years. For the first 18 months, assessments every 3 months included administration of the BPRS and Clinical Global Impression (CGI) (Guy, 1976) by a psychiatrist; a side-effects checklist (Guy, 1976), the Extrapyramidal Rating Scale (EPRS) (Simpson *et al*, 1964), and the Abnormal Involuntary Movements Rating Scale (AIMS) (Guy, 1976) by a second psychiatrist; the CGI and EPRS by a nurse; and a Social Scale (Stevens, 1973) by a social worker. The assessors were blind to the evaluations of other assessors and all previous assessments of their own. All assessors were blind to the depot dosage throughout, as this was managed by a separate psychiatrist. From 18 months to 36 months, assessment intervals were increased to 6 months, and assessments were made by a single psychiatrist on mental state alone, using the BPRS and CGI. At the conclusion of the trial, the hospital notes and prescription sheets of all patients were examined. In addition, the patients were seen at any time at their request, or if changes were noted by any treating agency.

Relapse was defined as a definite increase in or re-emergence of symptoms resulting in either a CGI score of 3 (moderate severity) or an increase of the BPRS score of >3.

Wilcoxon's Matched Pairs Signed Ranks and Mann–Whitney *U* tests were used for statistical analysis throughout, with one exception, which has been identified, and on that occasion the chi-squared test with Yates' correction was used.

Results

Essential data was lost on one patient (group B (half dose)), so the analysis is based on the remaining 59 patients.

The demographic characteristics of the sample are presented in Table I. No significant differences were found between the two groups on entry into the study (demographic features, previous treatments, previous dose of drug, mental state, symptoms, or side-effects).

TABLE I
Demographic features of the patient sample

	Group A	*Group B*
Age: years		
Range	20–66	20–65
Mean	42	40

Range	2–22	2–72
Mean	7.4	12.3
Total time on drugs: years		
Range	1.2–17	1.75–15
Mean	5.6	6.5

For the first 12 months, the doses in weekly equivalents were as follows:

Group A	range 4–20 mg;	mean 9 mg
Group B	range 1.7–10 mg;	mean 6 mg.

Analysis of the results for the first 12 months (Table II) showed that nine patients in group B (half dose) relapsed (one at 2 months, three at 3 months, and one at each of 4, 8, 9, 10, and 12 months), compared with three patients in the group A (full dose) (one at each of 4, 6, and 9 months); $P<0.05$ (chi-squared with Yates' correction, $\chi^2=4.11$).

In the survivors of the first 12 months, there were no differences in mental state. The scores on the CGI and BPRS were equal for all subscales and individual items. On the Social Scale the mean total fell during the 12 months in both groups, but the improvement for group B (half dose) was slightly greater (NS). In general this group showed a greater capacity for improvement, with more items showing

*$P<0.05$ (Wilcoxon's Matched Pairs Signed Ranks and the Mann–Whitney *U* Test).

a reduction in score. Only the item 'relatives' anxiety' showed a significant difference, with the group B (half dose) having more improvement at 6 months and 9 months (mean change 0.24 *v.* 0.52 and 0.24 *v.* 0.55; $P<0.05$), but this group had slightly higher scores on entry (0.26 *v.* 0.50; $P=0.06$).

There were no significant differences in the first 12 months in the risks for extrapyramidal symptoms, tardive dyskinesia (TD) or other measures of side-effects (Table II). On the AIMS the mean total scores and individual item scores tended to fall in both groups. In group A (full dose), the number of patients with clinical TD remained constant at seven, but a reduction occurred in the group B (half dose) from nine to seven patients. On the EPRS the mean total score fell in group B (half dose) but remained constant in group A (full dose) (NS). Akathesia scores fell in both groups but tremor (0.23–0.36 *v.* 0.25–0.05), rigidity (0.00–0.14 *v.* 0.11–0.05) and hypokinesia (0.019–0.25 *v.* 0.21–0.11) increased in group A (full dose) and fell in group B (half dose) (NS). On the side-effects checklist both groups showed a reduction in total incidents (group A (full dose) 55%); (group B (half dose) 65%), with a considerable variation over time, but the patterns of individual side-effects were similar in both groups.

A comparison of the first 6 months on reduced dose for each group (group A, 12 months to 18 months; group B, 0 months to 6 months) revealed no significant differences between the groups in mental state, relapses, or extrapyramidal symptoms. However, in group A, who had been on a full dose 12 months longer than group B, there was a significant reduction ($P<0.05$) on the AIMS, compared with an initial reduction at 3 months (NS) followed by a slight increase at 6 months in group B (Table II). Significant differences were also noted in social function. Group A showed a slight trend for the total score to increase, with a particular increase in item 'dissatisfaction felt by next of kin' (mean change 0.269, $P<0.05$). In contrast, group B improved, with reduced scores at both 3 months and 6 months ($P<0.05$). On individual items, this group had a significant fall in 'relatives' anxiety' (mean change 0.52, $P<0.001$). The true significance of the differences in social function, particularly at the 5% level, must be questioned, since group A had a lower total score on entry (NS) and therefore a reduced capacity for improvement.

During the principal study, from 0 months to 18 months, when the full assessments were carried out, no correlations were found between dose and absolute score or change in score for mental state, social functions, or extrapyramidal side-effects in either group. For group A (full dose) from 0 months to 12 months, the AIMS scores correlated negatively with dose ($0.01<P<0.05$). This implies that the patients on lower doses had higher reductions in scores. From 12 months to 18 months (i.e. following dose reductions), the AIMS total scores for this group correlated positively with dose ($0.001<P<0.01$). This suggests that patients on the higher-dose regimens experienced the greatest reduction in symptoms. Collectively these changes suggest that the patients originally on the highest doses benefited most from having their doses halved.

There were no differences in the additional drugs prescribed to the two groups from 0 months to 18 months (anticholinergic drugs 9 *v.* 7; benzodiazepines 5 *v.* 4; anti-depressants 1 *v.* 1).

Ten patients had three or more assessments before relapse. There was a slight trend for the total BPRS scores to increase prior to relapse, with a general increase in the items of affect. The numbers of patients who experienced change with any one item was small, with depression (four patients) showing the most frequent change.

From 18 months to 36 months, assessments were restricted to the CGI and BPRS every 6 months, together with a review of all notes on completion of the study. Therefore it was possible during this period for patients to experience an adverse change in their mental state, requiring a change in treatment, without meeting the full criteria of relapse, since partial or complete remission may have taken place before the next review. At 36 months, group A (with 25 patients completing follow-up) had been on a reduced dose from 12 months to 36 months, and group B (with 23 patients completing follow-up) from 0 months to 36 months.

It was found that 56% of group A and 70% of group B had met the full criteria of relapse, and 76–78% of all patients had been prescribed an increase in their neuroleptic medication to at least the level of their former full dose.

Discussion

The principal comparison is the 12-month double-blind prospective comparison of a standard dose *v.* half-dose reduction. Even though this dose reduction was less than in previous studies, these results confirm that it is not possible to make a substantial dose reduction in maintenance therapy without a significant increase in the risk of relapse (10% *v.* 32% at 12 months). The longer prospective follow-up with slightly less strict monitoring reports a relapse rate of 56–70% after 2–3 years on the reduced dose, with three-quarters of the patients resuming their original full dose. The evaluations for group B at 18 months and for both groups at 36 months confirm the observations of Marder *et al* (1985) that 12 months' is too short a period of assessment for the real risk of increased relapse to be known. It is particularly important to note that the sample studied was of patients in a stable mental state with low BPRS scores and good social function on a moderate dose of medication.

It has been suggested that, despite an increased risk of relapse, there may be advantages for the use of low-dose maintenance therapy. Both Kane *et al* (1983) and Marder *et al* (1985) speculated that relapses might be milder and more readily controlled. In this study a prodromal development was suggested in both groups over 6 months, but it is unlikely that acute relapses can ever be regarded as 'mild', since the consequences of an acute relapse, particularly for stable, good-prognostic patients such as this sample, are more substantial than commonly recognised.

The previous studies noted either a lower prevalence of tardive dyskinesia or a lower rate of symptom emergence in the low-dose group. These results are also suggested by this study. Although there were no statistical differences in abnormal movement scores for over the period 0 months to 12 months in group B (half-dose), there was a slight reduction of TD at 3 months, followed by a slight increase at 6 months. In group A there was a significant fall in TD during the 6 months following half-dose reduction ($P<0.05$), with no evidence of a withdrawal rebound.

Suggestions have been made that patients may either have improved levels of social function or feel more comfortable on low-dose regimens. The results of the present study are complex and do not indicate a clear advantage with either dose prescription in social function among survivors. Side-effects, including extrapyramidal side-effects, were less on a reduced dose, but no analysis showed changes of statistical significance.

Within the dose ranges used, both at the standard and reduced dose level, no correlation was found between actual dose prescribed and any measurement of outcome or unwanted effects.

The results of this study demonstrate once again that low-dose strategies, even a modest 50% reduction, have an unacceptably high risk of relapse for schizophrenic patients in general. However, it is recognised that individual patients can occasionally survive on very low dose prescriptions. The only suggested advantage for a 50% reduction in dose was the possibility of a reduced risk of tardive dyskinesia. Perhaps patients who either already have TD, or have been identified as being particularly at risk, might be placed on low-dose prescriptions, provided that they are fully aware of all the considerations. At this level of dose reduction, the previously claimed advantages of improved patient comfort and function were not evident.

Previous studies have suggested that for stable out-patients the standard dose of fluphenazine decanoate (Kane *et al*, 1983; Marder *et al*, 1985) is in the range 12.5–25 mg every 2 weeks (or equivalent). This study suggests that, for similar patients, 20–40 mg flupenthixol decanoate every 2 weeks (or equivalent) is the likely range.

Acknowledgements

We would like to thank Lundbeck Limited for a generous grant and assistance in the statistical analysis of the results. In particular our thanks go to Dr J. M. Simister and Celia Osborne (Biostatistician).

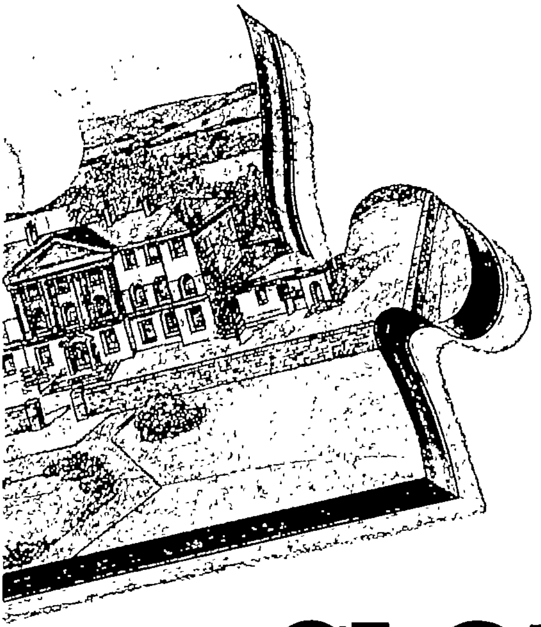
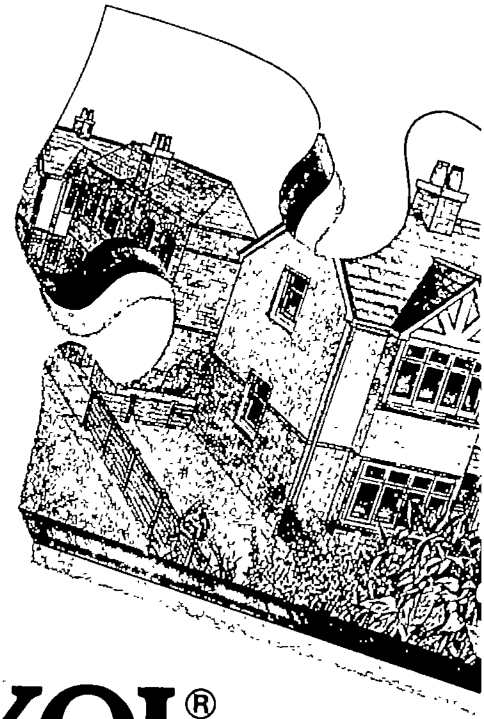
From Clinic to Community

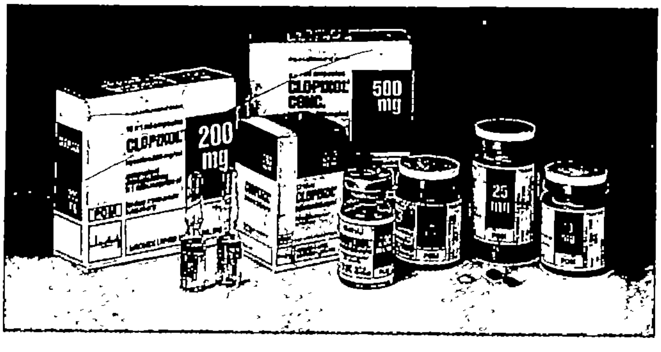




CLOPIXOL®

zuclopenthixol dihydrochloride/decanoate

TABLETS • INJECTION • CONC INJECTION



PRESCRIBING INFORMATION

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.

Indications Psychoses

Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses. Not recommended for children.

Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.

Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerance to other neuroleptics. Pregnancy (relative). Use with caution in patients with Parkinsonism, severe arteriosclerosis, senile confusional states; serious renal, hepatic or cardiovascular disease.

Overdosage Overdosage should be treated by gastric lavage.

Package Quantities and NHS Price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00.

PL Nos 0458/0027,0028,0029. PA Nos 115/5/3,4,6.

CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.

Indications Psychoses, especially schizophrenia.

Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.

Not recommended for children

Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment

Contraindications Comatose states.

Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.

Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur. (b) By sedation (with benzodiazepines) in the unlikely event of agitation or excitement. (c) By noradrenaline in saline intravenous drip if the patient is shocked.

Package Quantities & NHS Price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.03, 5 x 500mg (1ml) ampoules £36.23.

PL Nos 0458/0017,0041. PA Nos 115/5/1,5,7

ing 50mg fluvoxamine maleate, imprinted with 'Duphar 291' Pack of 60 tablets, basic NHS price
. **Uses:** Treatment of those affective disorders characterised by persistent low mood, impaired
motor activities and psychosomatic complaints **Dosage and Administration:** The tablets should
allowed without chewing and with water. Adults: The effective daily dose usually varies between
and 200mg and should be adjusted to the individual response of the patient up to a maximum of
. The minimum recommended starting dose is 100mg given in the evening. A total daily dosage in
of 100mg should be given in divided doses Elderly. The same dosage regimen may be utilised in the
as in the general population. Children: There are insufficient data to recommend the use of Faverin in
n. **Contra-Indications, Warnings, etc:** Faverin should not be given together with or within two
of terminating treatment with monoamine-oxidase inhibitors. Patients with hepatic or renal
iency should begin treatment with a low dose and be carefully monitored. Faverin has no effect on
motor skills associated with driving and operating machinery. However, in combination with alcohol
mpairment may be seen. Use in pregnancy and lactation There has been little human use but there
en no adverse animal evidence Avoid in pregnancy and in nursing mothers if a better known and safer
tive is available, although safety in pregnancy is likely. Interactions with other drugs. In interaction

Faverin. Care should be taken when Faverin is prescribed to patients already receiving propra
warfarin as the dose of these drugs may need to be lowered. No interactions were seen with digox
atenolol. **Side-effects:** The commonest symptom observed with Faverin administration is naus
usually diminishes early during the course of treatment. Other treatment emergent symptoms
during clinical studies were somnolence, constipation, agitation, anorexia and tremor. Other report
are often associated with the illness and their incidence in controlled trials is comparabl
experienced with placebo Faverin may cause a decrease in heart rate. During treatment, limited c
repolarization were observed in the ECG, but no causal relationship could be demonstrated. The in
postural hypotension was similar to that seen in patients treated with placebo. Treatment of overd
specific antidote is known The stomach should be emptied as soon as possible after tablet inge
symptomatic treatment should be given The use of medicinal charcoal is also recommended.
Quantities 50mg tablets. available in packs of 60 (3 strips of 20 blister-packed tablets). **Product**
Number 50mg tablets. 0512/0070. Further information is available from: Duphar Laboratorie
Duphar House, Gaters Hill, West End, Southampton SO3 3JD. Tel: Southampton (0703) 472281.

Double-Blind Study of Imipramine versus Phenelzine in Melancholias and Dysthymic Disorders

J. VALLEJO, C. GASTO, R. CATALAN and M. SALAMERO

In a 6-week double-blind trial, the efficacy of imipramine and high dose phenelzine were compared in the treatment of Major Depression with Melancholia, and Dysthymic Disorder (DSM-III). Both drugs were found to be equally efficacious in the treatment of 32 patients suffering from Major Depression. In 32 Dysthymic patients, phenelzine in high doses was found to be superior to imipramine. The clinical implications of these findings are discussed.

In the treatment of the endogenous depressions, the efficacy of the monoaminoxidase inhibitors (MAOIs) (Rees & Davies, 1961; Hamilton, 1982; Medical Research Council, 1965) has been less well established than that of the tricyclic antidepressants (TADs) (Klein & Davies, 1969; Morris & Beck, 1974).

In the case of the so-called neurotic and atypical depressions, the efficacy of pharmacotherapy is less clear. Earlier evidence in favour of the MAOIs (West & Daly, 1959; Robinson *et al*, 1973) has been qualified by more recent work showing that comparative results can be obtained with TADs (Nies & Robinson, 1981; Rowan *et al*, 1982). In one study, however, phenelzine was shown to be superior to imipramine (Liebowiz *et al*, 1984).

This paper reports a double-blind trial comparing imipramine and phenelzine in the treatment of DSM-III-diagnosed Major Depressions with Melancholia, and Dysthymic Disorders.

Method

Subjects

Selection of 83 subjects from a population of 116 unmedicated out-patients was made by two psychiatrists according to the following entry criteria: (a) age range 18–63; (b) diagnosis of Major Depression Episode with Melancholia, or Dysthymic Disorder (DSM-III); (c) absence of severe physical disease, on-going medical treatment and pregnancy; (d) absence of psychopathic/sociopathic disorder; Briquet's syndrome; alcohol/drug abuse; psychotic illness and bipolar, obsessive–compulsive, somatoform, panic, eating, and phobic disorder (DSM-III); (e) score of >16 in the Hamilton Rating Scale for Depression; and (f) ability to give real consent.

The 83 patients were assessed further and given placebo medication for a week. Ten improved and were excluded; the remaining 73 (melancholia, 34; dysthymic disorder, 39) entered the study. Each clinical group was then randomly allocated to imipramine or phenelzine in a double-blind 6-week design. Medication and placebo was given in tablets of identical appearance.

The following daily drug protocol was used: first week, imipramine 100 mg or phenelzine 30 mg; second week, imipramine 150 mg or phenelzine 45 mg; third week, imipramine 200 mg or phenelzine 60 mg; fourth to sixth weeks, imipramine 250 mg or phenelzine 75 mg.

All patients were asked to observe the MAOIs food precautions. Medication was given at breakfast and lunch time. No patient was allowed to take other medication except ten who required diazepam (5 mg *nocte*) for sleep disorder.

The patients were rated weekly for side-effects and compliance. During these contacts their medication was dispensed in seven small boxes. At the end of the trial, all patients were retested.

Instruments

The following rating scales were used: (a) Hamilton Rating Scale for Depression (HRSD); (b) Zung Self-Rating Depression Scale (in the Spanish translation by Conde) (ZDS); (c) Eysenck Personality Inventory (EPI-B).

Neuro-endocrinological tests

Dexamethasone suppression test (DST) was performed on all patients. Plasma cortisol was estimated at 4 p.m. after the administration of dexamethasone (1 mg) the night before at 11.30 p.m.; exclusion criteria as specified by Carroll *et al* (1981) were used.

Statistical analysis

Data were analysed by means of Student's *t*-test, chi-squared or Fisher's Exact Test. Patients in each clinical group were randomly subdivided and the coefficients of variability (Snedecor's Test) were compared to ascertain that there were no significant differences.

Results

Of the 73 patients who entered the drug trial, nine dropped out – seven from the Dysthymic Disorder group (four on

TABLE I
The two clinical groups compared

Characteristics	*Melancholic group (n = 32)*	*Dysthymic group (n = 32)*	*t or χ^2*	*Significance*
Sex				
Women	24 (75.10%)	28 (87.5%)		
Men	8 (25.0%)	4 (12.5%)	$\chi^2 = 1.641$	NS
Mean age: years	44.3 (s.d. 10.3)	40.2 (s.d. 11.5)	$t = 1.506$	NS
Socio-economic status				
Lowest	22 (68.8%)	24 (75.0%)		
Middle	8 (25.0%)	8 (25.0%)		
Highest	2 (6.3%)	0 (0.0%)	$\chi^2 = 0.309$	NS
Mean scores				
HRSD	25.1 (s.d. 5.2)	20.5 (s.d. 4.0)	$t = 3.937$	0.01
ZDS	57.4 (s.d. 9.0)	57.5 (s.d. 6.4)	$t = 0.046$	NS
EPI neuroticism	15.9 (s.d. 3.1)	15.7 (s.d. 4.3)	$t = 0.233$	NS
EPI extroversion	8.5 (s.d. 2.8)	6.8 (s.d. 3.4)	$t = 2.149$	0.05
Duration of disorder: months	8.0 (s.d. 1.8)	36.6 (s.d. 4.1)	$t = 36.131$	0.001
DST				
Suppression	19 (59.4%)	31 (96.9%)		
Non-suppressors	13 (40.6%)	1 (3.1%)		$P = 0.0002$

imipramine and three on phenelzine) and two from the Major Depression with Melancholia group (one on imipramine and one on phenelzine). The reasons were that one Major Depression with Melancholia patient (on imipramine) developed a delusional syndrome and had to be admitted for ECT; and the other eight patients abandoned the trial on account of side-effects (mainly hypotension). No significant differences were found on any variable between the drop-outs and the patients completing the study. The final sample consisted of 32 patients with Major Depression with Melancholia and 32 with Dysthymic Disorder.

The melancholic and dysthymic groups could not be differentiated in terms of sex, age, social class, ZDS or EPI neuroticism scale (Table I). The melancholic sample, however, showed higher mean scores on the HRSD (25.06/20.53) and the EPI extroversion scale (8.5/6.8). It also contained more DST non-suppressors (40.6%/3.1%). However, the duration of current episodes was longer for the Dysthymic Disorder group (36.6/8.0 months).

The groups differed significantly on ten HRSD items: depressive mood, early awakening, work and activities, retardation, agitation, gastrointestinal somatic symptoms, loss of weight, insight, diurnal variation of mood, and obsessive and compulsive symptoms. They also differed on two ZDS items: improvement in the evening and loss of appetite.

Imipramine versus phenelzine in Major Depression with Melancholia

For the Major Depression with Melancholia patients, comparison between those on imipramine (16) and those on phenelzine (16) showed no difference on any variable except sex ($P < 0.018$) (there was only one male in the imipramine group as against seven in the phenelzine group). Likewise the two groups showed no difference on final assessment (Table II). The variance of HRSD scores in the imipramine group was significantly smaller than in the phenelzine group ($F = 2.555$, $P < 0.05$). There was a tendency for the HRSD scores to be lower in the imipramine group than in the phenelzine group, but the difference did not achieve statistical significance.

The effect of imipramine was more marked on the following HRSD items: suicide ($P < 0.03$), retardation ($P < 0.005$), hypochondriasis ($P < 0.03$) and diurnal variation of mood ($P < 0.03$).

Imipramine versus Phenelzine in Dysthymic Disorder

Among the Dysthymic Disorder patients, no significant difference was found between those on phenelzine (16) and those on imipramine (16). Significant differences were found on final assessment on all rating scales except EPI extroversion (Table III): the phenelzine group had lower scores on the HRSD ($P < 0.05$), ZDS ($P < 0.01$) and EPI (neuroticism scale) ($P < 0.02$). HRSD item analysis showed imipramine to improve depressive mood ($P < 0.02$) and phenelzine to enhance work and activities ($P < 0.07$).

Discussion

Our data may help to solve earlier controversies. While the satisfactory response to both antidepressant drugs shown by the melancholic group is not surprising, it is of interest that the dysthymic group behaved to a certain extent in the same way.

TABLE II
Major Depression with Melancholia patients: drug subgroups compared (post-treatment values)

ZDS	43.06	9.02	34.88	7.40	2.804	0.01
EPI neuroticism	15.38	4.11	11.75	3.53	2.680	0.02
EPI extroversion	7.75	3.55	10.63	4.61	1.980	NS

It could be argued that this similar response by the two clinical groups reflects the fact that our sample of Dysthymic Disorder was 'overpurified' by the exclusion of subjects suffering from sociopathy, obsessive-compulsive disorders, anxiety, phobia and hysteria. This view can be accepted without reducing the value of our findings, and it can be concluded that our results apply only to a specific subpopulation of Dysthymic Disorder.

A technical objection to our study may be that it includes no placebo group. The decision to do so was taken on three grounds. First, imipramine and phenelzine are well-tried antidepressants. Secondly, the objective of the trial was not to show that these drugs were superior to placebo. Thirdly, all patients had already received a placebo during the selection week. Furthermore, compliance was strictly controlled.

The Major Depression with Melancholia group

The Major Depression with Melancholia patients responded equally well to both drugs. HRSD symptom reduction in the imipramine group was 71.4% and in the phenelzine group 58.2%, and ZDS symptom reduction was 37.7% and 31.8% respectively. The smaller difference detected by the ZDS (5.9% as opposed to 13.2% in the HRSD) suggests that it is a less sensitive instrument than the HRSD; on the other hand, it may simply result from the fact that ZDS scores depend upon patient self-scrutiny and not, like the HRSD, on objective clinical assessment. The standard deviation for the HRSD scores was smaller in the imipramine group; this reduced scatter may reflect a more homogeneous action by this drug.

The difference in terms of phenelzine efficacy between the present trial and the Medical Research Council trial (1965) is explained by the fact that our sample included neither patients with bipolar disorders nor psychotic depressives, and by the fact that our patients received higher drug dosage (75 mg daily) than those in the MRC trial (60 mg); in this respect our results coincide with those of Rees & Davies (1961) and Hamilton (1982), who used high dosage.

It can be concluded that Major Depression with Melancholia without psychotic symptoms responds equally well to imipramine and phenelzine, provided that high doses of the latter are used. Phenelzine should be considered as a good alternative to tricyclic antidepressants in cases when these drugs are contraindicated, cause major side-effects, or prove ineffective.

The Dysthymic Disorder group

In relation to Dysthymic Disorder patients, previous studies have tended to show MAOIs to be less effective (Young *et al*, 1979) or at best to have similar therapeutic action to TADs (e.g. amitriptyline *v*. phenelzine) (Nies & Robinson, 1981; Rowan *et al*, 1982; Paykel *et al*, 1982).

Our study shows phenelzine to be significantly superior. The standard deviation for the HRSD scores was smaller in the phenelzine group; this reduced scatter may reflect a more homogeneous action by this drug. However, the fact that imipramine also reduced symptom scores (50.3% in HRSD and 25.3% in ZDS) suggests that TADs are an adequate alternative when MAOIs prove ineffective or cause major side-effects. It is also of some interest to note the effect of phenelzine on the neuroticism (19.1%) and extraversion scores (47.2%) of the EPI. This suggests that these scores are contaminated by mental state.

The clear-cut nature of the results obtained in this study can be explained, firstly, by the fact that patient selection was strict (this also may explain the divergence between our results and those of Paykel *et al* (1982)); and secondly by the fact that our patients received a high dose of phenelzine. Higher doses may also explain the positive findings of Liebowitz *et al* (1984) (in panic disorder and hysterical dysphoria) when compared with those of Nies & Robinson (1981), who used lower doses.

It can be concluded, therefore, that in the treatment of Dysthymic Disorders, differences in favour of phenelzine appear only when high doses are employed, and care is taken to exclude psychopathic and hysterical personalities.

HRSD item analysis shows imipramine to have more effect on depressive mood and phenelzine more on work activity. In contrast to other studies (Nies & Robinson, 1981; Rowan *et al*, 1982; Paykel *et al*, 1982), we did not find any specific action of phenelzine on anxiety, although the scores on the EPI may show some trend in this direction. It is possible that the use of specific anxiety scales might have provided us with better data on this point.

The final conclusion of this study must be, therefore, that imipramine and phenelzine are effective in Major Depression with Melancholia and Dysthymic Disorder; and that phenelzine is more effective in the latter.

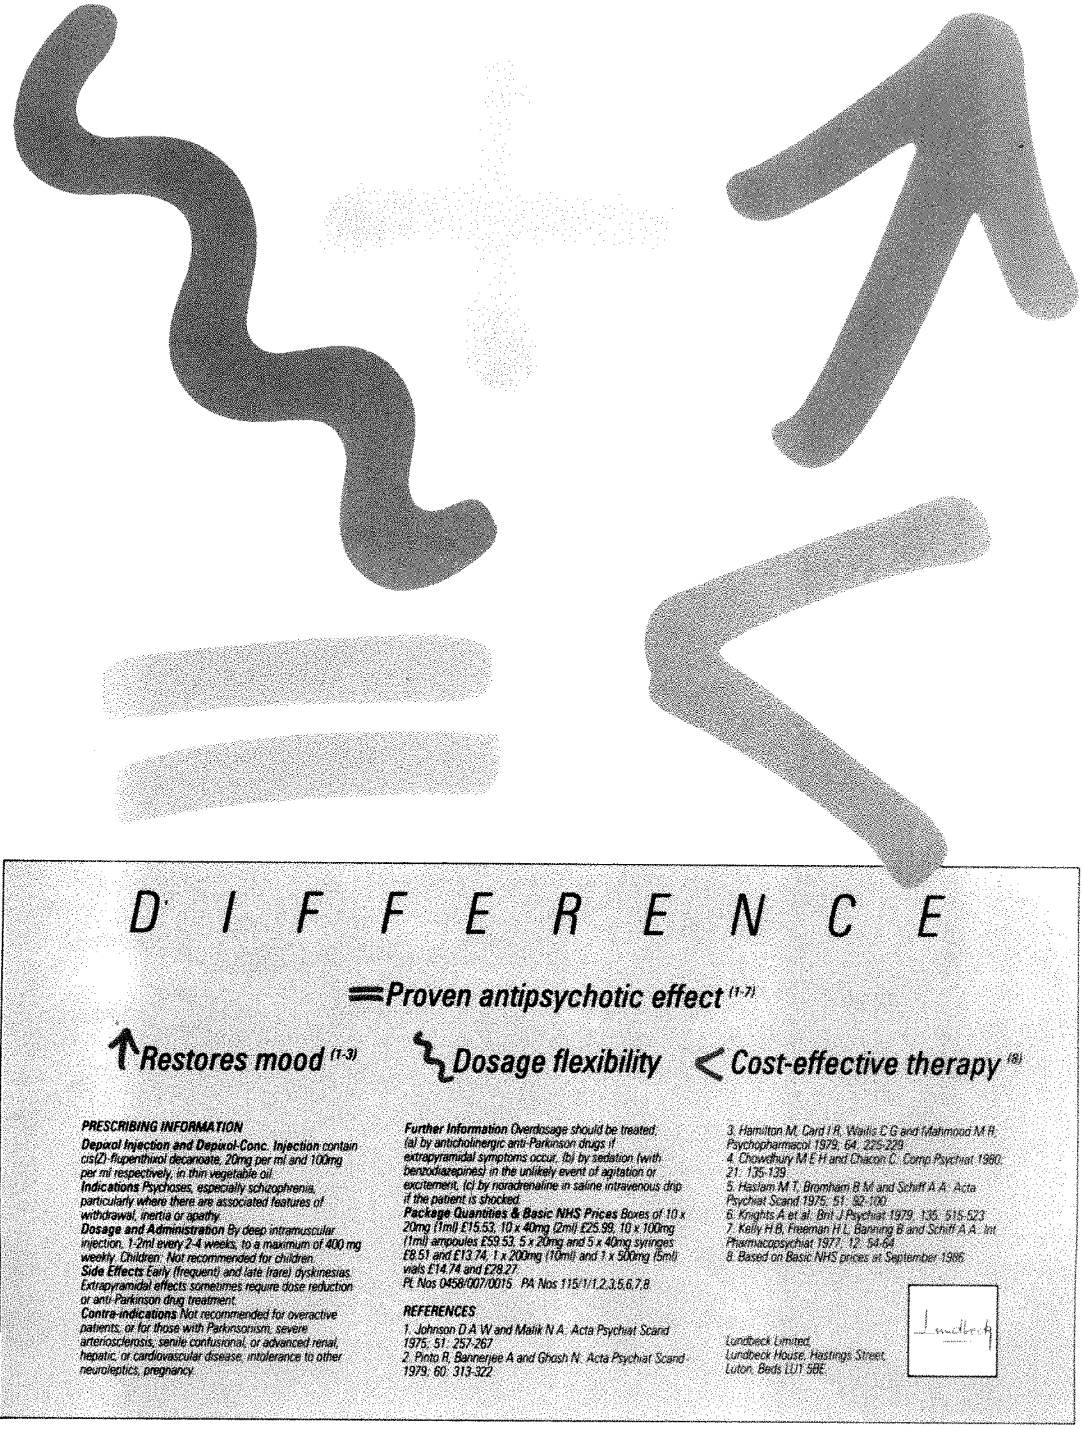
THE DEPIXOL

cis(Z)-flupenthixol decanoate



DIFFERENCE

= Proven antipsychotic effect (1-7)

↑ Restores mood (1-3) **~ Dosage flexibility** **< Cost-effective therapy (8)**

PRESCRIBING INFORMATION

Depixol Injection and Depixol-Conc. Injection contain cis(Z)-flupenthixol decanoate, 20mg per ml and 100mg per ml respectively, in thin vegetable oil.

Indications Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy.

Dosage and Administration By deep intramuscular injection, 1-2ml every 2-4 weeks, to a maximum of 400 mg weekly. Children: Not recommended for children.

Side Effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson drug treatment.

Contra-indications Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusional, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy.

Further Information Overdosage should be treated; (a) by anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur, (b) by sedation (with benzodiazepines) in the unlikely event of agitation or excitement, (c) by noradrenaline in saline intravenous drip if the patient is shocked.

Package Quantities & Basic NHS Prices Boxes of 10 x 20mg (1ml) £15.53, 10 x 40mg (2ml) £25.99, 10 x 100mg (1ml) ampoules £59.53, 5 x 20mg and 5 x 40mg syringes £8.51 and £13.74, 1 x 200mg (10ml) and 1 x 500mg (5ml) vials £14.74 and £28.27.

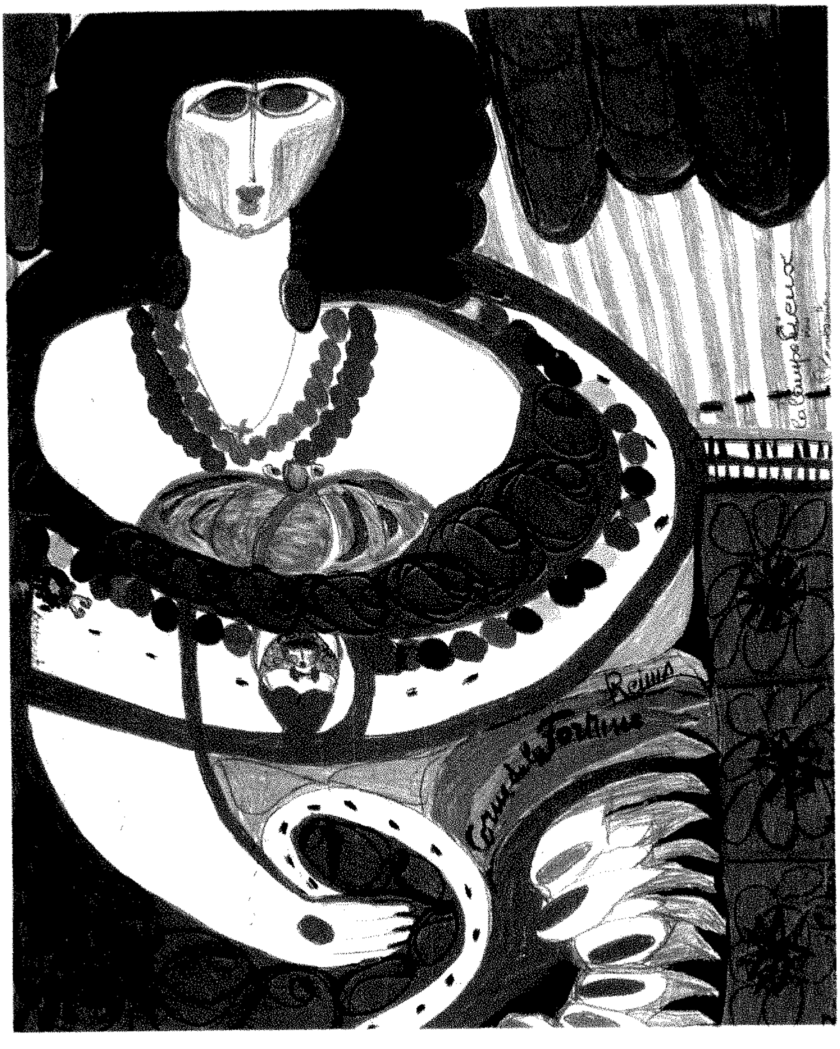
AN EXPRESSION OF SCHIZOPHRENIA.

Aloise was diagnosed as schizophrenic at the Cery Asylum, Lausanne. She was later transferred to the Asylum de la Rosiere where she remained for over 40 years until her death in 1964.

During the last 20 years of her life she worked steadily at her drawings.

The illustration below is produced with kind permission of the Musee Cantonal Beaux-Arts, Lausanne.



A TREATMENT.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol, it has become widely established throughout the world as an effective anti-psychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration of action following a single deep intramuscular injection.

In mild symptomatology the dosage for Haldol* Decanoate is from 50-100mg given 4-weekly, whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation[1] and a reduced requirement for antiparkinsonian medication,[2] leaving him/her better able to participate in other forms of therapy.

100mg/ml

HALDOL*

haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

Presentation: Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses:** As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side effects, precautions, contra-indications:** Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side effects: In common with all neuroleptics, the following side effects may be observed, sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Occasional local reactions such as erythema, swelling or tender lumps have been reported. In common with other anti psychotics, haloperidol has been associated with rare cases of neuroleptic malignant syndrome. **Dosage:** Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. An initial dose of 50mg every 4 weeks is recommended increasing if necessary after 2 weeks by 50mg increments to 300mg every 4 weeks. The dosage should be tailored to suit the individual patient and to reflect previous oral dosage. In adults 100mg Haldol* Decanoate is approximately equal to 500mg chlorpromazine (or equivalent) per day. Caution is required with the elderly, starting doses of 12.5mg to 50mg monthly should be tried first. **Product Licence Numbers:** 0242/0095, 0242/0094 **Basic NHS Cost:** 1ml x 100mg/ml x 5 £24.00 1ml x 50mg/ml x 5 £15.60. (Correct at time of printing). Further information is available on request from: **Janssen Pharmaceutical Limited**, Grove, Wantage, Oxon OX12 0DQ.

PHARMACEUTICAL LTD

COMPREHENSIVE PRIVATE PSYCHIATRIC TREATMENT

St. Andrew's Hospital offers a complete range of psychiatric treatment programmes for:

Acute Psychiatric Disorders
Eating Disorders
Alcoholism
Behaviour Disorders
Psychogeriatrics

Set in 100 acres of parkland, easily accessible from Junction 15 of the M1, the hospital has extensive recreational and sporting facilities.

St. Andrew's has an associated unit in North London, **Bowden House Clinic** is located in the village of Harrow-on-the-Hill, within easy reach of central London. The Clinic offers treatment for all acute psychiatric disorders.

For further details, write or telephone:

Self-Appraisal, Anxiety and Depression in Women

A Prospective Enquiry

J. G. INGHAM, N. B. KREITMAN, P. McC. MILLER, S. P. SASHIDHARAN and P. G. SURTEES

Depressive illness is known to be associated with low self-evaluation, but it has been suggested that there may be a reciprocal connection as well, such that low self-appraisal (in the absence of illness) makes the subsequent onset of depression more likely. A prospective study, using a community sample of 376 women, provided data about clinical state over a period of 18 months, and self-appraisal questionnaire scores were determined on two occasions separated by 6 months. There was no evidence that low self-evaluation predicted future episodes of depressive illness, except in women who reported previous psychological episodes for which they had sought medical help, and, even for those with previous episodes, much of the predictive power of low self-esteem was accounted for by individuals who were subsequently recognised to have been in the early stages of illness. Conversely, there was little evidence that prior episodes predicted future illness in people with high self-esteem. One explanation of the findings is that recurrent episodes of illness cause progressive impairment of self-appraisal, but other possibilities are also considered. Women who had recovered from illnesses detected at the first interview still had significantly less self-confidence 6 months later than those who were well throughout.

The link between negative self-appraisal and affective disorder is well known and documented. What is not clear, however, is the extent to which negative self-appraisals such as low self-esteem play any causal role in the genesis of illness. A recent study of self-esteem and self-confidence in women presented evidence of the influence of some social factors on self-esteem in the absence of illness (Ingham *et al*, 1986). These factors included the lack of a close confidant, and early separation from the mother, both of which are among the 'vulnerability' factors postulated by Brown & Harris (1978) as predisposing towards depressive illness. These findings may be taken as a partial confirmation of the latter authors' suggestion that impaired self-evaluation was the common intervening variable between their vulnerability factors and depression. However, although this cross-sectional study provided some support for the Brown & Harris hypothesis, the effect of the social variables on self-esteem was very small when compared with the effect of major depression itself.

Moreover, the association between self-esteem and vulnerability factors may have nothing to do with the causation of depression. There is a link missing from the chain of reasoning. The theory clearly states that low self-esteem existing beforehand will lead to the onset of illness, given other appropriate circumstances. It is thus necessary to establish that low self-esteem has some predictive power. There has been little previous work on self-esteem as a predictor, and what has been done is not very encouraging (Lewinsohn *et al*, 1981).

The theory also implies that low self-regard persists in depressed patients after recovery from illness. The main weight of evidence indicates a return to normal levels (Mayo, 1967; Caine, 1970; Hamilton & Abramson, 1983) unless the follow-up occurred soon after recovery (Foulds, 1976).

While analysing the cross-sectional data we noticed that reports were appearing indicating that it is the presence of negative self-evaluation that is linked with vulnerability to depression, rather than the absence of positive self-evaluation (Brown & Bifulco, 1985; Warr & Jackson, 1983; Parry, personal communication). The usefulness of the distinction was confirmed in our own cross-sectional study, and has been maintained in the present enquiry.

Aims

The aim of the present study was to test predictions from the Brown & Harris theory by a follow-up of cases and non-cases derived from a general population survey. Initial assessments were obtained for all those who were well to see whether those who subsequently became ill had significantly lower self-appraisal beforehand. Similarly, those who had been cases at the outset were re-assessed to determine whether they maintained their relatively low self-evaluation even after recovery.

There was also an obvious opportunity to confirm previous evidence, already strong, that new onsets of either anxiety or depression result in a decline in self-evaluation.

Thus the hypotheses to be formally tested were as follows:

Hypothesis 1. Women who are not cases but who are low in self-appraisal are more likely to become depressed subsequently.

Hypothesis 2. Women who have recovered from an affective disorder (depressive illness or anxiety state) have lower self-appraisal than those who have not been ill.

Hypothesis 3. Women who become ill with anxiety or depression suffer a decrease in self-appraisal.

For testing hypothesis 1, two self-appraisal scales (see below) were used and the same strict criterion was at first applied as was used in the cross-sectional study (Ingham *et al*, 1986). This was that both scales should show the predicted difference between means at the 5% confidence level. As will be seen, the criterion was later relaxed for further exploration of the data. The standard scales, and the sub-scales comprising negative and positive items, were considered separately. For testing hypotheses 2 and 3, only one scale was available and the usual 5% criterion was applied.

Method

Design

As already indicated, the study is a follow-up of a sub-sample of the women who had taken part in a cross-sectional survey of affective disorders reported in several earlier publications (Dean *et al*, 1983; Surtees *et al*, 1983; Ingham *et al*, 1986). The sample selected for follow-up comprised:

(a) all those who had been diagnosed as cases on either the Research Diagnostic Criteria or Present State Examination criteria for current psychiatric disorder
(b) all those who had one or more of a set of factors that were thought to be possible predictors of vulnerability to affective disorder
(c) a 40% random sample of the remaining women who were neither ill nor had any of the vulnerability factors.

The vulnerability factors were lack of close social support, lack of diffuse social support, poor relationship with one or more household members, living with three or more children aged under 14, living alone, loss of a parent before the age of 11, unemployment of spouse or cohabitee, previous contact with health services for 'nerves', and low self-confidence.

An important component of the research was the identification of women who were not 'cases' at the first assessment but who became ill at any time during the follow-up, which always extended for 6 months and generally for a full year after the initial assessment. A total of 415 women (cases and non-cases) were selected at the start of the study. At the 6-month point, 376 (91%) were successfully re-interviewed, and of these all but 43 were seen at 12 months as well. Details of the initial sampling are contained in the earlier publications. Data obtained at each interview were sometimes incomplete, and for this reason the tabulations show slight differences in sample size depending on which variables are being analysed. For the same reason there may also be slight discrepancies between the numbers reported here and those in other published tables concerning different aspects of the same survey. Similarly, other analyses, not reported here, have included nine women interviewed at the second follow-up but not at the first.

Interview

All the interviews were conducted by a team of interviewers specially selected and trained to undertake the initial survey (for further information see Surtees *et al*, 1983; Ingham *et al*, 1986). There was a further short period of training before the first follow-up interview. As far as possible interviewers followed up respondents they had seen before, but this was not always practicable and approximately 40% of the respondents were seen by a different interviewer.

Psychiatric assessment schedule

The psychiatric assessment schedule comprised the first 40 items of the Present State Examination (PSE) and additional questions from the Schedule of Affective Disorders and Schizophrenia (SADS) so that CATEGO and Research Diagnostic Criteria (RDC) could be applied (Wing *et al*, 1974; Spitzer *et al*, 1978). Where appropriate, and in particular when there was evidence of anxiety or depression, a standard procedure was used to determine the times of onset and remission of symptoms as accurately as possible. For determining current psychiatric status at each interview the normal PSE procedure was used, enquiring over the past month, but in addition enquiries were made which covered the 6 months preceding each interview (Surtees *et al*, 1986*b*). A final assessment, using all three schedules (in some cases only two were available), was then made in which dates of onset and remission were determined for each episode of illness throughout the period of study, together with its diagnosis. For each interview point, therefore, it was possible to define psychiatric status either as it was seen at that time or, with hindsight, as finally revised. The two were not always identical and we have used them both in ways that will be indicated. Other choices could have been made but we do not believe our conclusions would have been altered materially, except in the one instance where both analyses have been presented.

Self-ratings of anxiety and depression

For self-rating of anxiety and depression, visual analogue scales were used requiring each subject to mark her position on a 10 cm line representing severity. They have been described more fully by Miller & Ingham (1979).

Assessment of self-appraisal

The first interview included two widely used scales of self-appraisal, the Rosenberg Low Self-Esteem Scale (Rosenberg, 1965) and the Foulds and Bedford Lack of Self-Confidence Scale (Bedford & Foulds, 1978). A modification was introduced into the Rosenberg scale, to increase the likelihood that it would measure a relatively long-term characteristic rather than be over-influenced by short-term mood states. To this end the words "most of my life" were inserted into each of the statements in the scale, making it consistent with the Lack of Self-Confidence Scale.

The overall score from each scale was calculated as prescribed by its originator. Rosenberg used combinations of items that he claimed formed a Guttman scale; we used a simple sum of these combined items. The scales have been described in more detail by Ingham *et al* (1986).

Each scale had an equal number of positively and negatively worded items and it was a simple matter to split them into separate scales. An example of a positively worded item from the Rosenberg scale is

Most of my life, on the whole, I have been satisfied with myself

Strongly agree Agree Disagree Strongly disagree

A negatively worded item is

At times during most of my life I have thought I was no good at all

Strongly agree Agree Disagree Strongly disagree

Items were allotted scores of 1 to 4. The positive score was the sum of all five positive items, giving a range of 5 to 20, and similarly for the negative scale. Since a high score on the positive scale indicates low self-esteem, the scores on the negative scale were reflected for comparability.

An example of a positively worded item from the Foulds–Bedford scale is

Most of my life I have felt as capable as other people

Never Seldom Often Nearly always

A negatively worded item is

Most of my life I have been very unsure of myself

Never Seldom Often Nearly always

Again scores of 1 to 4 were allotted; each scale comprised three items, giving a range of 3 to 12. In this case a high score on the negative scale indicates low self-confidence, so the positive scale was reflected. Thus a high score on any of the scales tabulated indicates low self-appraisal.

After the first interview a decision was taken to shorten subsequent interviews, so the Rosenberg scale was dropped. As mentioned above, this meant that only one scale was available for testing hypothesis 2 and 3, and the usual 5% criterion was applied. The main reason for retaining the Foulds–Bedford scale in preference to the self-esteem scale was for comparability with other Edinburgh studies.

Results

Hypothesis 1

"Women who are not cases but who are low in self-appraisal are more likely to become depressed subsequently."

This is a prospective hypothesis predicting from information available at the first interview.

An initial problem arose concerning the status of a group of 11 individuals not initially recognised as cases who were subsequently reclassified, using information obtained at later interviews, as cases having onsets before the first interview. In nine of these there was evidence at the first interview that anxiety or depression was present during the previous month but symptoms were insufficient, in number, severity or duration, to meet the case criteria; in the other two, symptoms were not elicited at the time but the later data were judged to be more dependable. A strictly prospective position requires us to use a classification based only upon information available initially in selecting the sample of non-cases on which to make predictions. It can also be argued, however, that the 11 doubtful individuals should be excluded from the sample of non-cases on the grounds that they were subsequently shown to have been ill. This matter has been referred to in two earlier publications dealing with different aspects of the same study (Surtees *et al*, 1986*a*,*b*). We shall first adopt the strictly prospective position and then demonstrate the effect of taking the alternative viewpoint.

Table I gives the means and standard deviations, on the self-assessment scales at the time of the first interview, of respondents who were not then recognised as 'cases'. It compares those who became cases during the 12-month follow-up (including the 11 'doubtfuls'), subdivided by RDC diagnosis, with those who did not. There is a clear tendency for those who became cases to have had lower self-esteem or self-confidence at the time of the first interview. Analysis of variance produced significant *F*-ratios for the Rosenberg scale (*P*-values are shown in the table), but by the *a priori* criterion (which requires significant differences on both the Rosenberg and Foulds–Bedford scales), hypothesis 1 is not verified, either for combined or for separate sub-scales.

The analysis could end at this point but it is unwise to dismiss the hypothesis entirely. As all the mean differences are directionally consistent with the hypothesis, and the *F*-ratios for the Rosenberg standard and negative forms are statistically significant, further exploration of the data is suggested. Deviant scores were most marked for those who became major depressives, and separate *t*-tests showed that even on the two Rosenberg scales, it was only they who differed significantly from the women who remained free from illness. There were no significant differences in the scales based on positively worded items, but the future major depressives had larger variances on all six scales. *F*-ratios showed that the variances on each measure were significantly larger for this group than for those with no new episodes. This is a complicating factor in the analysis. If it is taken into account, the significant *t*-values for Rosenberg standard and negative scales are reduced, and remain significant with only a 1-tail test. However, the

1. Slight variations in sample size result from missing values.

difference in variance is itself an interesting finding, which tends to support the hypothesis.

Thus overall the evidence so far is of some limited support which falls short of our preset level of statistical significance for hypothesis 1. Negative self-appraisal does appear to contribute something to the onset of depressive illness, although it is not a spectacularly successful predictor. In so far as it is operative at all, it remains to be determined whether negative self-regard might be better viewed as a reflection of some other predictive variable.

Emotional state at first interview

It is possible to hold a continuum concept of psychiatric illness. From this point of view, some of the people who were not recognised as cases at interview 1 may nevertheless have had an increased level of distress placing them some way towards the arbitrary threshold discriminating cases from non-cases. The visual analogue rating scales of anxiety and depression provided some evidence on this point. On both scales, the mean scores of those who were subsequently to become cases were significantly elevated. If marked negative self-appraisal is only found in women who are already on the way to becoming diagnosable cases, the meaning of hypothesis 1 is markedly altered. However, analysis of covariance, adjusting for variations in both anxiety and depression scales, did not alter the findings materially and the significant variations shown in part (a) of Table I remained.

So far, the 11 individuals who were not recognised as cases initially but were later reclassified have been included among the new onsets. The data were next re-analysed from the alternative viewpoint, excluding the 11, leaving 299 of the 310 respondents. The differences in standard and negative Rosenberg scales then became non-significant. The 11 doubtful individuals can be regarded as sub-clinical at the first interview, and their self-appraisal at that time could be part of the incipient illness.

Effect of prior medical contacts

'Vulnerability', as defined by the presence of any one of the seven factors stated, had been incorporated into the design to increase the likelihood of detecting new-onset cases. In the event, this was largely unsuccessful, as the 'vulnerable' sample did not produce a significantly higher proportion of new cases than the remainder (Surtees *et al*, 1986*b*). However, one group was selected because of previous contact with health services for 'nerves', and there was a strong indication that they did have a higher proportion of new onsets. The implications of this for the interpretation of Table I were examined by logistic regression analysis (Baker & Nelder, 1978), a technique which permits examination of the separate components in a multivariate analysis when the outcome is classified in simple categories. It was only possible to consider outcome (the response variate) in binary form, and since the link between self-appraisal and onset was clearly established only for major depression (Table I), the division was fixed accordingly to separate new onsets of major depression from the rest of the sample. Self-appraisal was taken as one predictor and previous contact with the health services for 'nerves' was another. The results are shown in Table II and also for Rosenberg standard and negative scales in Table III with the 11 sub-clinical cases excluded. In the column headed 'unadjusted' are scaled deviances of new

TABLE II

Prediction of 23 new onsets of major depression in 310 subjects not recognised as cases at first interview

onsets accounted for by each factor taken separately and ignoring all other factors. In the next column, previous contact has been adjusted for Rosenberg negative scale; reciprocally each of the self-appraisal measures has been adjusted for previous contact. The scaled deviances are distributed as χ^2 with degrees of freedom shown in the tables.

The results in Table II confirm those in Table I and show, furthermore, that the standard and negative Rosenberg scales retain their predictive power even after adjustment for previous contact. For the negative scale, it is the adjusted interaction term that is most striking. Table III shows again the lack of a significant self-appraisal effect with the 11 excluded, and the predictive power of prior health service contact shows up very clearly. The nature of the effects that underlie the pattern shown in Tables II and III is further demonstrated in Tables IV and V, in which the Rosenberg negative scale has been divided arbitrarily into three categories. Negative self-appraisal is associated with previous medical consultations for nervous disorders ($\chi^2 = 8.86$, d.f. 2, $P<0.02$). The significant interaction effect with respect to onset of illness shown in Table II is evident from Table IV, indicating that the negative scale predicts new onsets in those who have had previous consultations but does not do so for those with no prior treated episodes. Similarly, prior contact predicts illness only in those tending to low self-esteem. The effect is reduced, however, when the 11 sub-clinical cases are excluded from the sample.

In all these analyses we have distinguished three categories of previous health service contact, as shown in the tables, but it appears that it is previous psychiatric consultation which is the more powerful predictor of new episodes. If the 11 sub-clinical cases are excluded, as in Table V, it is the only significant predictor, and the effect of GP contact becomes non-significant. As a *post hoc* exercise, the analysis in Table II was repeated, using only two categories for prior contact – those with and without a history of consultation with a psychiatrist – and it was then found that the effect of negative self-esteem was significant irrespective of treatment status (the interaction term became non-significant). This result should be interpreted with extreme caution pending replication, and it remains the case that there is no evidence that low self-esteem predicts new onsets

TABLE IV

New onsets of major depression (23 in 310 subjects) in different categories of self-appraisal (Rosenberg negative items) and health service contact for 'nerves'

Health service contact	*Rosenberg negative items*			
	Most negative (scores 13–20)	*Intermediate (scores 11–12)*	*Least negative (scores 5–10)*	*Subjects*
No contact	2/26 (7.7%)	2/49 (4.1%)	8/120 (6.7%)	195
GP contact	4/16 (25.0%)	0/25 (0.0%)	1/38 (2.6%)	79

Psychiatric contact	3/8 (37.5%)	2/13 (15.4%)	1/14 (7.1%)	35

in women who have not sought medical help for psychological problems.

Summary for hypothesis 1

The findings have not verified hypothesis 1. There is, however, some indication that negative self-esteem may help to predict new episodes of major depression in women who have already had prior health service consultation for psychological symptoms. (An alternative possibility, to be discussed later, is that prior contact only operates as a predictor in women with low self-esteem.) The predictive power of low self-esteem is reduced when women in a sub-clinical stage of illness are eliminated from the sample, but the failure to reach significance may result from smaller numbers. These distinctions will be considered further in the discussion section.

Hypothesis 2

"Women who have recovered from an affective disorder (depressive illness or anxiety state) have lower self-appraisal than those who have not been ill."

At follow-up, to keep the interviews as short as possible, the Rosenberg scale and other parts of the schedule had been discarded. Women who had been recognised initially as cases and who had recovered before the second interview tended to show lower scores on the Foulds–Bedford indices (greater self-confidence) on the second occasion, but still had significantly higher mean scores than people who remained non-cases over the 6-month period. Table VI shows means and standard deviations for all those who had been cases at any time during the period, distinguishing those who had recovered and those who had not. Both have significantly higher mean scores than non-cases, as shown by the F-ratios from separate analyses of variance. Thus hypothesis 2 was supported: women who have recovered from affective illnesses lack self-confidence when compared with others who have not been recent cases. A covariance adjustment for anxiety and depression scales at the time of the second interview reduced the differences between groups slightly, but they remained significant for standard and positive scales. A further analysis showed no evidence that the scores of recovered cases were affected by either the duration of the episode or time since recovery.

Hypothesis 3

"Women who become ill with anxiety or depression suffer a decrease in self-appraisal."

As expected, women who became cases after the first interview showed a fall in self-confidence on the Foulds–Bedford measure (statistically significant for standard and positive scales) when compared with non-cases, who tended to change in the opposite direction. Hypothesis 3 is thus also supported and, as a corollary, unrecovered or relapsed cases had very significantly greater mean scores (lower self-confidence) than non-cases at the follow-up (Table VI). This time, in contrast with recovered cases (see previous paragraph), a covariance adjustment for anxiety and depression scales did eliminate all three significant differences.

Additional findings

Our initial interest in self-appraisal was as a possible link between vulnerability factors and illness (Ingham *et al*, 1986). Two of Brown & Harris's vulnerability factors (absence of confidant and childhood separation from mother) were associated with low self-appraisal in a sample of people who were not ill at the first interview, but neither of these factors was a statistically significant predictor of new onsets in the present study.

The number of children under 14 in the home predicted new onsets significantly when onsets were defined to include any disorder of anxiety or depression (major or minor, see Table VII). It became non-significant, in a logistic regression analysis, after adjusting for low self-appraisal. However, the confidence level was changed only marginally by the adjustment ($P<0.10$), and when the analysis was repeated with number of children represented as a dichotomy (two or more/less than two), its effect remained significant even after adjusting for low self-appraisal. The latter cannot be claimed to be an important mediating element.

Marital status was also a predictor of new onsets, but retained its predictive power when similarly adjusted. Unemployment of husband, after making the necessary adjustments for marital status, was also a significant predictor of new onsets, and also remained so after self-esteem was controlled. Table VII summarises the findings. Hence,, whatever the mechanism by which marital status and unemployment of the husband conduce to new illnesses, self-esteem does not appear to have an important role.

TABLE VI
Scores at second interview

	Standard form			*Foulds–Bedford scale* *Negative items*			*Positive items*		
	n	*Mean*	*s.d.*	*n*	*Mean*	*s.d.*	*n*	*Mean*	*s.d.*

Discussion

Our intention has been to discern whether indicators of low self-regard can predict subsequent depressive and other illness episodes. We have not set out to explore a full interaction model by including data on life stresses and adversity, but rather have confined ourselves to testing the three hypotheses set out earlier in the paper.

The conclusions to be drawn concerning the role of self-appraisal must hinge on the adequacy of the measures used, especially those assessing self-appraisal *per se*. The two instruments employed have all the limitations of standard questionnaires. Moreover, a little reflection suggests that self-esteem is a complex concept which must involve a number of components with possibly discrete psychological meanings. On the other hand, the instruments used are well established and extensively researched. Both scales distinguish normal subjects from those with depression at high levels of discrimination, and are also able to reflect differences in social background and early environment among normal individuals. Details have been given elsewhere (Ingham *et al*, 1986). For the present, the scales appear adequate for exploratory purposes.

The "most of my life" phrase was inserted into the Rosenberg statements to reduce the likelihood that the scale would be susceptible to short-term fluctuations. Such a device does not seem to be completely successful, as present results with the Foulds–Bedford scale have shown. Without it the scales may well have reflected prodromal depressive states to a greater degree, but it is unlikely that other results would have altered materially.

Using the Rosenberg scale we have found, as have previous writers (e.g. Brown & Bifulco, 1985), that it is people's tendency to make negative statements about themselves that is associated with depression. There was no such link with the absence of positive statements. Warr & Jackson (1983), who used a scale similar to our own, including some Rosenberg items, showed the same differential link (between positively and negatively worded items) with unemployment, which is also associated with depression (Surtees *et al*, 1983).

The three Foulds–Bedford scales, however, show a different pattern. Neither the standard form, nor either of its components, is a predictor of new onsets. Furthermore, it was the positive scale that showed a significant lowering of self-confidence at the second interview in new-onset cases. There is little point in speculating on the reason for this anomaly, but in comparing the scales there are two obvious differences that may be relevant. The first is that the Foulds–Bedford sub-scales contain only three items each and may consequently be less reliable than the Rosenberg sub-scales. Secondly, the difference in wording of possible responses between the two scales may be significant. It should be noted, however, that most of the differences between group means are in the predicted direction.

The findings prompt some general speculation concerning the relationship between depression and low self-esteem. Like all other investigators, we found a major fall in self-esteem with the onset of depressive illness, especially major depressive illness, whether the levels are compared with the individual's own pre-morbid level or with general population norms. It appears that the magnitude of the drop is closely related to the intensity of the depressive or anxious mood change. In this context, then, low self-esteem is intimately related to the illness itself. The temporal relationship between the drop in self-esteem and the onset of symptoms is not clear, but the results from our 11 'sub-clinical' cases suggest that the fall occurs at an early stage. It might well be one of the earliest manifestations of depression, and one of the last to disappear. But in addition it is possible that low self-esteem, generally of less severity than is found during a phase of illness, can be a more enduring characteristic. As discussed in our earlier paper (Ingham *et al*, 1986), the principal evidence against this view is that recovered depressives are generally reported to regain normal levels of self-esteem. However, most investigations of this issue have been based on hospital samples, which are known to be atypical in many respects. In the present survey, recovered cases could still be distinguished on their self-esteem scores from those who had been well throughout. Moreover, this difference persisted, even adjusting for current mood – a necessary procedure since recovered individuals may well have had some residual symptoms. Nor was there any evidence among recovered cases that self-esteem was influenced by the time since recovery or the duration of the recent illness, insofar as we could determine the relevant dates. Thus several findings point to the same conclusion – that individuals liable to depressive illness, as witnessed by their history, are distinguished by chronic self-disparagement which is not explained by their anxious or depressive mood. The mechanism underlying the persistence of low self-esteem, if confirmed, still remains to be clarified.

Our present concern, however, is essentially with the predictive power of low self-esteem (hypothesis 1) in the population at large. In exploring this topic it became clear that low self-esteem predicted future illness only among those women with a prior history of a treated episode. The strength of this association varied somewhat according to how the 11 sub-clinical individuals were considered, but the general pattern was as shown in Tables IV and V. These may be read as showing that low self-esteem is predictive only among those with a prior history, or conversely, that a prior history is only predictive among those with low self-esteem. It is well established that a prior history is a potent predictor of new episodes, and the present data suggest that low self-esteem moderates this relationship in some way. It is unlikely that self-disparagement *per se* induces depression (since as already explained it has no predictive power for women without a previous history). Alternatively, it could be that recurrent episodes of illness leave their mark, as it were, by a progressive impairment of self-confidence which can be recognised between spells of illness, an effect which might be non-specific for any kind of recurrent disorder. More speculatively, low self-esteem might be little more than a correlate of other factors which determine recurrence of illness, although perhaps this possibility is less likely. Resolution of these alternatives must await closer study of the broader questions already adumbrated. Meanwhile, we conclude that for the majority of women, namely those with no known history of illness, self-concept is no pointer to psychiatric illness in the near future.

Finally, we briefly consider the role of chronic social adversity or vulnerability factors insofar as they relate to new onsets. The question is important, since in recovered cases it is possible that the persistence of low self-esteem after recovery (see above) might be due to the continuation of the adverse social stresses which triggered the illness itself; among those with no prior history, adversity might predispose to illness by first causing a loss of self-regard. Our numbers do not make detailed analysis possible, but, for the total sample, the results do not support the notion that the putative vulnerability factors described in the earlier cross-sectional study (Ingham *et al*, 1986) reduce the threshold to depressive illness by reducing self-esteem. The factors that were most associated with low self-esteem were not the ones that best predicted new onsets; and, conversely, two of those that did predict new onsets continued to do so after adjustment for self-esteem.

Acknowledgements

We are grateful to Dr Christine Dean, who took part in the earlier stages of the project and contributed substantially to its success; also to an anonymous referee for raising important issues that we have tried to take into account in revising the paper.

Marital Problems and Treatment Outcome in Depressed Women
A Clinical Trial of Social Work Intervention

ROSLYN H. CORNEY

In a clinical trial investigating the effectiveness of social work intervention with depressed women patients in general practice, 80 women were randomly allocated to an experimental group for referral to attached social workers or to a control group for routine treatment by their GPs. They were reassessed at 6 and 12 months. The results indicated that women who had major marital problems were more likely to be depressed at follow-up than those with good relationships. However, patients with marital difficulties in the experimental group made more improvement than the controls. Women initially assessed as suffering from 'acute on chronic' depression and having major marital difficulties were found to benefit most from social work intervention.

Marital disharmony and breakdown have a number of damaging ramifications both for the adults concerned and the children. It brings with it a higher risk of suicide, behavioural problems in children, and deterioration in physical health (Home Office, 1979; Dominian, 1980).

Depression and marital problems are also closely linked, although there is controversy as to their sequence (Briscoe & Smith, 1973; Brown & Harris, 1978). Paykel *et al* (1969) found that increases in marital difficulties and disputes were the most frequent 'life events' reported by depressed women in the 6 months prior to seeking treatment. In another study, Weissman & Paykel (1974) assessed the social adjustment of depressed female outpatients and compared them with a normal female population. They found that the depressed women had much more marital dysfunctioning than the normal women, characterised by poor communication, friction, disengagement, and sexual problems. In addition, these marked impairments persisted long after the women recovered clinically (Bothwell & Weissman, 1977). Other studies have suggested that women who lack close confiding relationships with their husbands or cohabitees are particularly vulnerable to episodes of depression (Miller & Ingham, 1976; Brown & Harris, 1978).

Research has indicated that more people approach their general practitioners with their marital difficulties than any other professional (Chester, 1971; Home Office, 1979; Mitchell, 1981; Brannen & Collard, 1982), presenting their problems either overtly or covertly, with symptoms of physical or mental ill-health. It has been advocated that general practitioners and the primary care team should be strengthened by the attachments of other professionals to deal specifically with problems such as these (WHO, 1973; Shepherd, 1974), and in recent years an increasing number of different professions have been attached, including social workers, clinical psychologists, community psychiatric nurses, and counsellors (Kincey, 1974; Hicks, 1976).

While there has been a considerable number of reports and subjective accounts on the advantages that these various schemes confer (e.g. Clare & Corney, 1982), there has been a lack of independent objective assessments of whether these schemes actually benefit the patients referred.

The aim of the clinical trial described in this paper is to investigate whether the attachment of a social worker to general practice can benefit depressed women of child-bearing age. As previous studies have found that clinical improvement is often directly related to marital improvement, this suggests that the treatment of depression should also include social intervention aimed at reducing marital difficulties and strife (Rounsaville *et al*, 1980). This paper, therefore, specifically focuses on the subgroup of women with marital difficulties, investigating their clinical outcome after 6 months and one year, and the effects of treatment.

Method

Following a pilot study to test feasibility, the main study was initiated involving the participation of six doctors. Five of these were based in a health centre with a social work attachment scheme involving four part-time social workers. This scheme had been in operation for 2 years when the study started and was well established. The sixth doctor was from a single-handed practice and had been involved in previous studies with this unit.

The doctors were asked to refer women aged 18–45 years presenting with 'acute' or 'acute on chronic' depression, whose symptoms of depression had appeared (in the case of the former group) or intensified (in the case of the latter group) in the previous 3 months. Women suffering from major physical ill health and those already seeing a social worker were excluded.

All referrals were initially interviewed by a psychiatrist, using the Clinical Interview Schedule (CIS; Goldberg *et al*, 1970). This schedule was developed specifically for use in community surveys and has been found to be acceptable to individuals who do not see themselves as psychiatrically disturbed. It includes a detailed enquiry into the severity and frequency of ten common symptoms (e.g. irritability, depression, anxiety) which are each rated on a five-point scale. The total symptom score is a composite rating obtained by adding these ten scores together. At the end of the interview, the psychiatrist rates the patient on the presence of 12 'manifest abnormalities' observed during the interview. These are each rated on a five-point scale and the scores are added together to form a composite 'manifest abnormality score'. A total score for the interview is obtained by adding the symptom score to twice the manifest abnormality rating. This method of scoring has been found to have the best agreement with clinical judgement. A rating of overall severity is also made. A score of 0 is not a case, 1 is subclinical, 2 a psychiatric case of mild degree (disturbance is just clinically significant), 3 a case of moderate degree, and 4 a case of severe degree.

Patients ascertained as obtaining a rating of overall severity of 2 or more who also fulfilled the age and chronicity criteria were referred to a social research worker using the Social Maladjustment Schedule (Clare & Cairns, 1978). This instrument includes a detailed marital assessment in which married and cohabiting women were rated on four items: shared interests and activities, sources of conflict, responsibilities and decision-making, and sexual compatibility. For women on their own the rating concerned the woman's relationship with her boyfriend or her attitudes towards the opposite sex and her opportunities for meeting men.

Patients were then randomly allocated to the experimental or control group by a research assistant who was not involved in the assessments. In order that the two groups were matched in certain characteristics, patients were allocated into one of eight sets according to two categories of age, married or single status, and whether they were suffering from an 'acute' or 'acute on chronic' depression. The first patient in any of these sets was assigned to the experimental or control group by the toss of a coin, the second patient was automatically assigned to the alternative group, the third patient randomly allocated and so on. Those allocated to the experimental group were referred to one of four attached social workers for treatment, while the controls were referred back to their doctors for routine treatment.

After 6 months, the women were reassessed by means of the same instruments. The research staff involved in these assessments were unaware of any intervening treatment. Additional information was obtained by placing a card in the general practitioner's notes. The date of any clinical improvement or deterioration, from the initial psychiatric assessment to one year later, was recorded, as well as the number of visits the patient made to the doctor and any psychotropic drug prescription. Details were also collected from the attached social workers, who completed specially designed forms regarding each client referred to them. These forms recorded the initial assessment of the social worker and the problems presented, and also details of the social worker's contacts with the client, the types of intervention given, and the reason for closure.

The results were analysed by means of univariate and multivariate analyses of covariance, taking into account the three matching variables and also the initial scores as covariates.

Results

Characteristics of cohort

There were 116 women referred to the study, of whom 104 attended for the first interview. Of these, 91 were assessed as suitable for inclusion in the study. Of the 13 women who were ineligible, nine were considered to be chronically depressed, two had depressions of insufficient severity, and two were already seeing a social worker.

Of the 91 eligible women, four refused the social interview and seven were unwilling to participate in the follow-up

TABLE I

Summary of initial characteristics of experimental and control groups

	Experimental group (n=41)	*Control group (n=39)*
Marriage		
Married women and cohabiting women: %	76	69
Women with major problems in their marital or sexual relationships: %	63	59
Work

interviews or had moved out of the area. Therefore, 80 patients were included in the study, 41 being allocated to the experimental group (existing services plus allocation to the social worker) and 39 to the control group (existing services only).

At the time of the initial assessment, the experimental and control groups were closely similar in respect of their demographic characteristics, and psychiatric, physical ill health and social ratings, and there were no statistically significant differences between them (Table I). Over two-thirds of both groups were married or cohabiting, and high proportions had major problems in their relationships with their husbands, cohabitees, or boyfriends (hereinafter called major 'marital' problems). Approximately 80% of each group were taking psychotropic drugs. Table I shows some of the initial characteristics of both groups.

Follow-up scores

When the women were re-interviewed 6 months later, approximately two-thirds were assessed by the psychiatrist as improved (i.e. given a severity rating of 0 or 1 on the CIS). However, the majority of women who had no major 'marital' problems had improved at follow-up, in comparison to only half of those with major problems in this area (Table II).

This difference was statistically significant at below the 1% level for the four follow-up composite clinical ratings (symptom score, manifest abnormality score, severity rating, and total score) using univariate analyses of covariance. The medical notes also revealed that women with no or minor 'marital' problems improved in health much quicker than those with 'marital' difficulties ($P<0.01$). The former were also less likely to be depressed one year after referral (Table II). However, this information was only available for 69 women, as 11 patients had moved and changed practices.

Although the quality of the patient's relationship with her sexual partner affected the clinical outcome, it was found to have no statistically significant influence on the improvement of social scores, on psychotropic drug prescription by the doctor, or on the patient's attendances at the surgery, as recorded by the general practitioner.

Effects of treatment

There was very little difference in outcome between the experimental and control groups after 6 months or one year according to the clinical data collected or the social or medical criteria.

Over 80% of both groups had taken psychotropic drugs between the two assessments, and there were no major differences between groups on the length of time patients were taking these drugs. Although at the time of follow-up assessment 22% of the experimental group were taking a psychotropic drug in comparison with 31% of the controls, this difference was not statistically significant.

Women with major 'marital' problems who received social work help made much more improvement than the controls (Table III). This interaction between treatment and quality of the patients' 'marital' relationship was found to be significant when a multivariate analysis of variance was performed on all the follow-up clinical scores ($P<0.05$), and for three out of four of the follow-up composite clinical ratings using univariate analysis of covariance ($P<0.05$; Corney, 1981*a*, 1985). However, there were no significant interactions on the social scores indicating improvement, or on psychotropic drug prescription or patients' attendances at the surgery.

TABLE IV

Proportion of patients improved after 6 and 12 months for 'acute' and 'acute on chronic' patients according to quality of 'marital' relationship

	Group 1 (acute on chronic; no or minor problems)		*Group 2 (acute on chronic; marked problems)*		*Group 3 (acute; no or minor problems)*		*Group 4 (acute; marked problems)*	
	Proportion	*(n)*[1]	*Proportion*	*(n)*	*Proportion*	*(n)*	*Proportion*	*(n)*
Proportion improved at 6 months (severity rating 0 or 1)

Further analysis of the data indicated that the chronicity of the patient's depression was another important variable in determining outcome. An important distinction between the patients included in the study is that some were 'acutely' depressed, having had symptoms of depression for 3 months or less, while others were assessed as 'acute on chronic', having had symptoms for a longer period. The results indicated that a much higher proportion of 'acute on chronic' patients improved if they were referred to a social worker. For 'acute' patients the reverse was true, fewer patients improving when referred to the social work service. This interaction between treatment and chronicity was also found to be statistically significant in a multivariate analysis of covariance ($P < 0.05$), and in the univariate analyses of three out of four of the composite clinical scores ($P < 0.05$).

Chronicity of illness, presence of marital problems, and treatment

As the analyses revealed that chronicity of the patient's depression and the quality of her 'marital' relationship were both important, further analyses of three-way interactions of these two variables and treatment were performed. These were statistically significant for univariate analyses of three out of four of the follow-up composite clinical scores ($P < 0.05$).

These findings suggested that one subgroup of patients benefited more from the social workers' interventions than the three other groups (Table IV). These were women who were assessed initially as having major 'marital' problems and who were suffering from 'acute on chronic' depression (group 2). With this particular group of women, 80% of the experimental group were assessed as clinically improved at follow-up in comparison with only 31% of the controls. This difference still held one year after referral when the medical notes were examined. Of the experimental group, 57% were judged by the doctor to be well, in comparison with 18% of the controls. In contrast, women assessed as acute on chronic who had no or minor 'marital' problems (group 1) fared less well in the experimental group than the controls, but there was no difference in outcome one year after the initial assessment.

For the acutely ill patients, there were fewer differences in outcome between the experimental and control groups. All those with no or minor 'marital' problems improved (group 3), while over half of those with a poor relationship failed to get better.

The majority of women who had improved clinically also made some improvement in their social adjustment; thus 'acute on chronic' depressed patients with major 'marital' difficulties who were referred to a social worker made more improvement in their social adjustment than the controls in this category. However, the three-way interactions for social work intervention were not statistically significant, either for social scores in general or for those scores measuring marital adjustment (Corney, 1981*a*).

Social contacts

The women were also asked about the number of social contacts they had. The women with major 'marital' problems also tended to have poorer social contacts. Over 40% of the women with 'marital' problems were rated as having poor social contacts in comparison with only 16% of the women who had no or minor problems. The results suggest that those women with poor social contacts benefited more from the additional help from a social worker, as more clinical improvement was made by patients with poor social contacts in the experimental group than those allocated to the control group. This interaction was significant, however, for only two of the four composite clinical ratings made at follow-up, and a multivariate analysis of variance was not possible. However, all five subjects in group 2 ('acute on chronic', major 'marital' problems) with poor social contacts improved in the experimental group, by contrast with only two out of eight of the controls.

TABLE V

Who helped most: numbers improved at 6 months for the four groups of patients studied

Initial and follow-up social scores

When the initial scores of the four categories of patients outlined in Table IV were examined, there was no evidence to suggest that the differences in outcome between the patients in the experimental and control groups for these categories were due to the initial social scores (Corney, 1981*a*).

The social workers' contacts with their patients and the nature of the intervention

As the previous results suggest that social work intervention was more beneficial to patients suffering from 'acute on chronic' depression, especially those with marked 'marital' problems, the social workers' activities were analysed, taking into account the four groups of patients outlined in Table IV.

The social workers also recorded in detail their activities performed either with the client or on behalf of the client. The social workers worked in a number of ways with these clients and were not given any specific guidelines. This was because the needs of the clients were remarkably varied: some women had few social problems while others had many. The social workers were asked, however, to try to see their clients on a regular basis, to make a contract with the client specifying frequency of interviews, and to agree on a plan of action regarding their work in the following months. They were also asked to limit their time of contact to the 6 months between assessments.

Communications with the clients were classified by the social workers according to the typology developed by Hollis (1964), which the social workers were familiar with using. The social workers used sustaining and exploring techniques with all the clients they interviewed, investigating the reasons why the patient was depressed as well as offering support and reassurance. The social workers also considered that in 90% of the cases they tried to develop their client's awareness and understanding of the dynamics of her personal situation, behaviour, and attitudes. In addition, the social workers tried to help some of their clients using behavioural techniques; for example, helping the client manage her depression by setting her a number of tasks to perform each day or devising a contract between husband and wife to increase co-operation between them.

In addition to the interventions, the social workers also gave some form of help concerning practical matters to over 40% of their clients. Of the 35 patients they saw, they gave information on practical issues to 15, they acted as an advocate or referred to other agencies for 8, and they gave substantial help to 2 women in the form of financial aid, holidays, day nursery placements, and council accommodation.

Although similar proportions of patients in all four groups received the different kinds of counselling identified, a higher proportion of patients in groups 2 and 3 received practical help.

Number of interviews

There was no general relationship between clinical improvement and the number of interviews given, but in many cases only a few interviews were given as the patient improved and further interviews were considered unnecessary.

Just over 60% of the patients seen by the social workers were interviewed alone. This was not usually due to decisions made by the social worker but due to the spouses of the patients often resisting involvement, or the patients' reluctance for their spouses to be interviewed. However, clients who were seen with their spouses did not improve more on ratings measuring marital adjustment or on clinical scores that those clients seen alone.

Motivation

At the end of their involvement with each client, the social workers were asked to rate the clients' motivation to be helped by them. The social workers assessed nearly 60% of the women in group 2 (Table IV) as highly motivated, in comparison with only 15% of the women in the other groups. This term was used by social workers when clients were willing not only to accept help but also to alter their behaviour or situation accordingly. The highest rate of improvement was found among the clients who were highly motivated; over 80% of this group had improved at follow-up.

Clients' assessment of help obtained

At the end of the second social assessment, the patients were asked if anyone had helped them, and they were given time to spontaneously mention one or more individuals. They were then asked who had helped most (Table V), and were questioned in further detail about whether they received help from their general practitioner or from a social worker.

Nearly 70% of the experimental group spontaneously mentioned one or more people as helpful (including spouse, friends) in comparison with only 45% of the controls. Two-thirds of those who saw a social worker spontaneously mentioned that she had helped them, especially those in groups 2 and 3.

When asked who had helped most, over 45% of the 35 patients who saw a social worker indicated that she had, particularly patients in groups 2 and 3 (Table V). The doctor, husband, friends, and relatives were mentioned by the control group as being the most helpful more often than by patients in the experimental group.

When the patients were asked specifically whether they had seen a social worker and whether it had been helpful, a further six patients thought she had been helpful. All but one of the 35 patients who saw a social worker had considered that the social worker had been understanding, and only two patients had found difficulty in talking to her. Generally, patients appreciated the help they received, with 80% mentioning the support given by the social worker. A third mentioned practical help or information, and the same proportion indicated that the social worker had helped them either "manage their depression" or increased "their understanding of themselves" or "helped in their relationships" (Corney, 1981*a*).

Discussion

The results suggest that the quality of the patient's marital relationship is a crucial factor affecting clinical outcome: women with marital difficulties were much more likely to be still depressed 6 months or one year after referral than women without these problems. These findings are in accordance with those found by Weissman and her colleagues in their study of depressed female out-patients (Rounsaville *et al*, 1980).

The results of this investigation suggest, however, that women with 'acute on chronic' depression who have marital difficulties may benefit from the help of a social worker. Compared with the controls, more patients in this subgroup who saw a social worker were not depressed at follow-up. The findings of other studies in this area are mixed. Weissman and her colleagues found that individual psychotherapy did not bring about any more substantial social, marital, or clinical improvement among individuals assessed as having "initial marital disputes", leading the authors to suggest that conjoint therapy might have been more appropriate (Rounsaville *et al*, 1979). Although some of the women in this present study received help together with their husbands, this was not built into the design of the trial and depended very much on the patient's wishes or those of her husband. There was no evidence to suggest, however, that conjoint therapy brought about additional improvement in clinical ratings or those scores measuring marital adjustment.

A study of task-centred social work conducted on self-poisoners who had recently been admitted into casualty with an overdose found that one of the major areas of improvement in the experimental group was the patient's marital and interpersonal relationships (Gibbons *et al*, 1978). Although no differences were found between the experimental and control groups in respect of repeated self-poisoning or of clinical criteria, the experimental group showed significantly more change than the controls in their social problems when assessed at 4 and 18 months after entry into the study.

Why did the social worker help patients in group 2 more than the others? Further analysis of the data of the present study, including details on the patients' social contacts and who they felt had helped, suggested that many of the patients with a poor marital relationship also had poor social contacts. Thus in many cases the patient not only could not talk to her husband but also had no one else in whom she could confide. This may be why this group of women so readily accepted the emotional support given by a social worker. The reason why the control patients in group 2 did so badly could have been due to their lack of support from others: over 70% felt no-one had helped them. In contrast, only one-quarter of the experimental patients in group 2 felt no-one had helped, and over half felt the social worker had helped most. Possibly, the lack of a difference between the outcome of the experimental and control groups in the other groups could have been due to the support the control patients received from relatives, husbands, and friends.

The results also indicated that the patients who gained most benefit were those who had been depressed for some time. The results, especially when considered in conjunction with a previous study of general practice patients, suggest that doctors should refer to social workers patients with more long-standing depressions and neuroses, as these will be helped more than those whose symptoms have a very recent onset (Cooper *et al*, 1975; Shepherd *et al*, 1979). When the patient's depression becomes acute on chronic, there is less chance of spontaneous recovery (Cooper *et al*, 1969; Kedward, 1969), and help from an outside agency may be necessary to bring about change. The patient may also be more likely to accept such help and act upon it.

Patients with acute depression appear more likely to recover without outside help. The additional help of the social worker may be unnecessary or even harmful, the social worker interfering with the individual's own mechanisms of coping or the support received from others. The patient may also be less motivated to receive the help offered, having become depressed only very recently, and may not be inclined to accept outside help or regard it as necessary. It is possible that very early intervention may therefore be inefficient, inappropriate or even harmful.

In this study the client's motivation to be helped by a social worker appears to be related to the length of time she has been ill and the help she receives from others. However, it is possible that the nature of the patient's social problems is another important factor affecting motivation. Patients in group 2 had more social problems than the others; many of these were practical matters, which may have been why so many of this group were eager for help.

The social workers carried out much more practical help on behalf of the clients in group 2 and contacted more agencies on their behalf. In the earlier study on chronic neurotic patients, where substantial differences were found between the experimental and control groups, the majority of the social work carried out was practical in nature (Shepherd *et al*, 1979). Although many social workers tend to stress their skills in counselling and underrate the practical help they can give (Wootton, 1978), the arrangement or provision of practical assistance by social workers may be of great value to general practice patients, including those who are depressed. Studies obtaining the clients' views of social work support this, clients appreciating most the combination of practical help with emotional support (Butrym, 1968; Mayer & Timms, 1970; Sainsbury, 1975; Corney, 1981*b*). Certainly the social workers' expertise and knowledge of practical resources are what specifically distinguish them from their other colleagues in general practice and can be used to argue their case for inclusion into the primary care term (Clare & Corney, 1982).

From the results of this study it seems reasonable to suggest that a further study should concentrate specifically on depressed women with marital problems using an 'attached' social worker with experience in conjoint marital therapy. The tendency of women with marital problems to become chronically depressed (Rounsaville, 1980) indicates the need for the development of effective treatment measures, resulting in both marital and clinical improvement.

Acknowledgements

This study was carried out as part of a research programme planned by the General Practice Research Unit at the Institute of Psychiatry, under the direction of Professor Michael Shepherd and with the support of the DHSS. I would like to thank Dr A. W. Clare, Dr B. Harwin and Dr P. Williams for their help in conducting the psychiatric interviews; the social workers, Mrs B. Bowen, Mrs Y. Davis, Mrs A. Rushton, and Mrs J. Winny; Dr G. Dunn, Dr V. Cairns and Mr D. Wiggins for statistical advice; the general practitioners at Woodside Health Centre; and Dr and Mrs J. Fletcher.

Caring and Its Burdens

A Study of the Spouses of Depressed Patients

GRAINNE FADDEN, PAUL BEBBINGTON and LIZ KUIPERS

Spouses of 24 patients suffering from persistent depression were interviewed to find out how they were affected by the patient's illness. These effects were marked, although mainly endured without complaint, and included restrictions in social and leisure activities, a fall in family income, and a considerable strain on marital relationships. Some of the behaviour shown by patients was hard to bear, and 'negative' symptoms such as misery, withdrawal, and worrying commonly caused problems. Few relatives, however, know how to deal with difficult behaviour. Despite this, the majority remained committed to staying with the patient. Spouses had a variety of complaints about the way they were handled by hospital staff, particularly about being deprived of information and advice. These results have considerable implications for the way in which relatives should be dealt with as part of the overall management of persistent depression.

Over a period of 30 years there have been several studies documenting the problems of relatives living with those who suffer from psychiatric illness. We have reviewed these studies and their impact elsewhere (Fadden *et al*, 1987). The general conclusion must be that relatives bear considerable burdens, often without complaint and at some detriment to their own mental health. They are used as sources of information but their own questions are left unanswered by the psychiatric team. They are rarely offered any service or advice and consequently have little understanding of the patient's illness. They frequently receive the impression that they are held responsible for the patient's state, without being given any idea of how they could modify aspects of their behaviour that might contribute to the patient's condition. This situation will not remedy itself, and is likely to worsen in the face of the continuing move towards community care.

Studies of the problems resulting from specific conditions have so far been concerned with the relatives of those with schizophrenia (Brown *et al*, 1966; Creer & Wing, 1974; Wing, 1982). The current study arose from a concern that the relatives of depressed patients might be exposed to similar difficulties. No previous investigation has focused on this group. Even the professional who intends well towards such relatives is constrained by ignorance of the problems they may face. We therefore sought to establish a typology of the burdens of living with depressed patients. Although the data do not purport to describe the absolute extent of burden, they do indicate the kinds of problems that might be experienced by these relatives, and thus increase the awareness of a clinical team willing to help them. In order to obtain the widest view of these problems, we chose to investigate separate groups of bipolar patients, unipolar 'endogenous' depressives, and neurotic depressives. As a result, clinical course varied from persistent misery to relatively discrete but more florid episodes.

The study is for the most part descriptive, and had a number of aims. It sought to portray the burden that results when a patient is unable to carry out expected roles because of a depressive condition. It aimed to document the types of behaviour and symptoms exhibited by the patient that are most difficult for the relative to deal with, and the ways relatives have of coping with such behaviour. The relatives' own psychological adjustment was assessed. The knowledge that people had about the nature, origin and possible outcome of their depressed relative's condition was recorded, and their opinion was sought of the service they themselves had received from the psychiatric team.

Method

Patients were obtained from the emergency clinic and out-patient clinics of the Maudsley Hospital. In-patients were only admitted to the study if admission was recent or they were still spending some time every week at home. The following selection criteria were used:

(a) living currently and at least for the two previous years with a relative

(b) onset of illness at least three years ago
(c) no organic disorder, forensic problems, or alcohol abuse
(d) at least three episodes of illness or persistent symptoms of a level likely to exceed the requirements of the Index of Definition threshold more than 50% of the time since first onset.

Twenty-four relatives, all of whom were patient's spouses, were interviewed. Originally it had been planned to interview any adult with whom the patient spent most time. However, as the first 16 patients who met all the other criteria for selection were in fact living with spouses, it was decided to select thereafter only those patients who were living with a spouse. It seems a reasonable assumption that depressed patients who live with someone are most likely to be living with a spouse. It is improbable that selection bias could account for the preponderance seen in this study.

Thirteen cases who were in scope (35%) were excluded because they, their spouse, or their consultant refused permission for the interview.

Patients were allocated to one of three groups according to their measures on the Present State Examination (PSE) (Wing *et al*, 1974; Wing & Sturt, 1978). The Syndrome Checklist facility was used where appropriate, and the clinical data were processed by the CATEGO and ID computer programs. The three groups were:

(a) 5 females and 3 males with bipolar disorder
(b) 3 females and 5 males with unipolar episodes falling into CATEGO class R or D
(c) 4 females and 4 males with neurotic depression (CATEGO class N); these had symptoms more than 50% of the time but did not meet the criteria for the first two groups; in fact they had numerous symptoms most of the time.

This grouping was deliberately chosen to permit the study of cases with significant recurrent or persistent depressive symptoms. In terms of the problems they are likely to pose for relatives, if not necessarily in terms of the level of symptoms, they are therefore those towards the more severe end of the spectrum. In only one case from the bipolar group was the patient ill at the time the spouse was interviewed. In the other two groups the patient was ill when the relative was seen in half of the cases. Bipolar patients tended, as might be expected, to have distinct episodes, and were also more likely to be prescribed prophylactic medication. The clinical characteristics of the patients are given in detail in Table I.

Patients were of representative social class, but 15 were either unemployed or retired. Overall mean age was 49, with the bipolar group averaging six years younger than this (Table II).

The allocation of relatives to the three groups was determined by the type of illness seen in the patient. The relatives' characteristics are given in Table III.

As no measures were available which served the specific aims of this study, a new schedule was devised* which was developed on the basis of the Social Behaviour Assessment Schedule (SBAS) (Platt *et al*, 1983), the shortened version of the Camberwell Family Interview (Rutter & Brown, 1966; Vaughn & Leff, 1976), an instrument used in the current Camberwell High Contact Survey, and the schedule used by Paykel *et al* (1982). The schedule thus constructed assessed role function and allocation, difficult behaviours, and the relative's knowledge about the patient's condition and opinion of the service received. Coping was assessed with a 17-item questionnaire based on 14 items used by Folkman & Lazarus (1980) and a further 3 items described by Pearlin & Schooler (1978). Most of the information was gathered by the interviewer asking questions within a

structured framework and rating the answers, after further probing if necessary, in accord with predetermined categories. The degree of perceived control over adverse situations was rated using a Likert scale. Relatives were also given the PSE.

Initial contact was made with patients through their consultants, and if they met the criteria listed above they were interviewed with the PSE as part of the allocation to the appropriate group. Contact was then made with the relatives. Most interviews were carried out at home, and in a quarter of cases it was not possible to interview the relative in the absence of the patient. This happened more often with bipolar patients. It could be argued that the more optimistic assessments of those married to bipolar patients arose partly because of these circumstances of the interview, but it is also possible that bipolar patients tended to stay in the interview *because* they were well. The interview involved the administration of the instruments described above, and usually lasted 1½–2 hours.

Results

The practical consequences of the patient's depression for the spouse

There were 83% of male and 42% of female relatives at work. Very few had had to make major changes in work routine because of the patient's illness, but nearly half said that they found work a strain as a result of their responsibilities towards the patient. Two women had been required to take up full-time employment because the husband's bipolar illness prevented him supporting the family.

There were 41% of relatives who said that the state of their finances was much worse since the patient became ill. Most loss of income came about because the patient was unable to work, and in the case of four male patients the drop in family income was over 50%. Families dealt with this by cutting down on leisure activities and holidays, and in a minority of cases by borrowing or owing money, breaking into savings, or cashing insurance policies. Nearly half of the patients' spouses had had to take over total responsibility for finances.

The social and leisure activities of relatives suffered considerably. There were 71% of spouses who had experienced at least some reduction in the number of their social activities as a result of the patient's illness. Nearly half said they never went out with the patient socially, although only one of the spouses of bipolar patients said this. This constriction of social activity was particularly marked when the patient was male. Spouses of unipolar and neurotic depressives also reported that the patient's depression meant fewer friends called to the house. In their view, friends had been put off by the behaviour of patients when ill, particularly by their silence or conversations limited to distressing or gloomy topics. A quarter of relatives now felt they had no-one to turn to for help or support, and half did not know of anyone in a position similar to themselves. Many were embarrassed and reluctant to tell people about the spouse's depression, being conscious of stigma.

Social isolation went hand in hand with the long stretches of time relatives spent in face-to-face contact with the patient, a mean of 65 hours a week, consistent across the three patient groups. There appear to be no normative data for comparison, but this mean exceeds what would be arrived at if the couple spent every evening and all weekend in the same room. Indeed, a third of relatives said they shared all their activities with the patient, although the proportion was smaller for bipolar patients and larger for neurotically depressed patients. Employment predictably reduced the amount of face-to-face contact.

Spouses were asked to assess overall changes in their marital relationship since the onset of depression. Such assessments clearly depend on a number of factors, including the duration, persistence and intrusiveness of symptoms and the spouse's capacity for coping with them. Nearly half the sample mentioned actual difficulties in their relationship (Table IV). Where difficulties were mentioned, the spouses of bipolar patients tended to rate them as less severe. Indeed, a minority of this group actually felt the illness had brought them closer together. The most likely reason for their relatives' tolerance is that only one bipolar patient was ill at the time of the study, although it could also have resulted from the intermittent course. Wives were more likely than husbands to perceive a deterioration of the relationship.

TABLE IV

Reported effects of depression on the marital relationship

	Total sample (n=24)	*Bi-polars (n=8)*	*Uni-polars (n=8)*	*Neurotics (n=8)*
More arguments	13	4	6	3
Spouse no longer talks about own worries	13	4	5	4
Less affection shown by patient	12	3	4	5
Difficulties in relationship	11	2	3	6
Difficulties in sexual relationships	10	5	3	2
No longer have sexual relationships	8	2	3	3
Have separated for a time	5	3	2	0

Spouses outlined the ways in which the relationship had changed: over half disclosed that they no longer felt able to talk to the patient about their own problems. This was because they didn't want to worry the patient, because their own worries appeared insignificant by comparison, or because they felt the patient would in any case be unable to offer support. More than half of the spouses, particularly wives, felt that they received less affection from their partners than before the illness. A third said that they had ceased sexual relationships as a result of the depression, and a further 42% reported difficulties in this area. Although a third of all spouses said they had difficulty keeping the relationship going, none of these was married to a patient with bipolar disorder. Nearly half the sample had thought of leaving at some stage, and it is of interest that these were mainly married to bipolar patients. Four husbands and one wife had actually separated from their spouses for a time.

Heavy drinking	2	8

Nearly half the couples had no children, and this was more likely if the patient was female. Where there were no children, in around half of cases this was attributed to eugenic considerations, to the patient's presumed inability to cope, to loss of libido, or to a combination of these factors. Only a quarter of couples had children who were still living at home, and it was therefore difficult to gain any coherent idea of how child care was affected.

Problem behaviour

Spouses were asked to indicate whether the patient exhibited any of 30 types of behaviour and whether these were a problem. The rating of a symptom as a problem depended on a combination of its persistence, duration, and intrusiveness but was probably also related to the spouse's ability to cope. Problem symptoms were of two broad types: social withdrawal and complaints; and somatic and florid types of behaviour. Apart from sleep disturbance, which 83% of spouses identified, the types of behaviour which were most often a problem fell into the first category (Table V).

The more florid features of depression were rarer and therefore less often seen as a problem. Not surprisingly, it was the spouses of bipolar patients who mentioned problematic florid symptoms. Many of the most commonly identified types of behaviour were also rated as severe in degree, but this was also true of the florid symptoms exhibited by bipolar patients.

As might be expected, the tendency to see behaviour as resulting from illness was greater for florid symptoms than for negative symptoms and complaints (Table VI). Appetite loss, odd and destructive behaviour, hallucinations, and violence towards others were not perceived by any relative as being under the patient's control, whereas other behaviour types were seen by a varying proportion of relatives as personality attributes.

TABLE VI

Coping

Many spouses used what might be called cognitive coping strategies, such as "wish the situation would go away" (92%) or "look for the silver lining" (58%). A third of spouses criticised or lectured themselves, and 29% made themselves feel better by eating, drinking, or smoking more.

Almost half of the spouses interviewed (45%) felt that they had no idea what to do in a practical sense to deal with the mood disturbance of the patient and its consequences for their lives, and in the case of relatives of neurotics this figure rose to three-quarters. Two-thirds of the total sample felt that they were unable to see things from the patient's point of view. Among relatives of patients with bipolar affective disorder, this figure was only a quarter, but the large majority of relatives of neurotic and unipolar depressives felt this way. At the same time, three-quarters of those interviewed reported that they did not talk to anyone to find out more about the situation.

The spouses of bipolar patients frequently reported that things had been difficult during the first episode as they did not understand what was going on. At that time, they often had particularly bad experiences – through the wild expenditure of the patient, for instance. They did, however, learn through these experiences, both to spot earlier when the patient was becoming ill, and to take precautions like assuming charge of the cheque book when it was apparent the patient was relapsing. It appeared these spouses found it easier to cope because episodes were distinct, even though they felt as if they were living with a different person at those times: their husband or wife would 'return' between episodes.

Half the spouses reported that they were kept going by the hope that the patient would be "cured" one day and 29% felt that their spouse would be "OK any day now". A third of spouses said that they sometimes felt they could not cope with the situation any longer and would have to find a way out, and three reported that they felt like that all the time. Such feelings were considerably commoner in wives than in husbands.

Psychological strains and adjustments in relatives

Relatives were asked about the psychological adjustments they had to make as a result of the patient's depression. Such adjustment could be related to changes in the patients, to consequential changes in the spouses' circumstances, or to changes in themselves.

Two-thirds of the sample reported feeling that the patient was a completely changed person as a result of the depression. Over half experienced a sense of loss, as if they had lost the husband or wife they had once had. This was least marked among the relatives of bipolar patients and most prominent among those of neurotic depressive patients and is therefore probably the result of relatively unremitting symptoms. The vast majority (88%) of relatives felt that they wanted to stay with the patient in spite of all these changes, although for some this came from a feeling of duty. Dissatisfaction with the changes was strongest among the relatives of bipolar patients. Nearly half of the spouses felt that the patient had become like a child to them, someone who needed to be looked after.

Almost three-quarters of relatives, particularly those married to neurotically depressed patients, reported that some of their hopes and dreams for the marriage had remained unfulfilled because of the patient's illness. Despite this, only two spouses reacted bitterly. Grief, guilt and sorrow were commoner reactions, each experienced by a third of the total sample, although not by the relatives of bipolar patients. A sense of grief was much commoner in wives (58%) than husbands (8%), the only reaction in which there was an appreciable sex difference.

The relatives of bipolar patients rarely perceived that changes had been wrought in themselves, whereas this was almost universal in the rest of the sample. However, the reported changes were very varied, falling into three categories. Some changes made the situation easier to bear: arguing less, giving in more often to the patient's wishes, thinking more before saying things. Others represented some kind of personal growth: becoming more independent, assertive or mature, being able to understand other people's worries better. Some changes, however, involved deteriorations in physical and mental health.

Nine spouses (37.5%) scored above level 5 of the Index of Definition. Bebbington *et al* (1981) give values of 10.9% from a community sample in Camberwell. However, several of the families in the present report came from more affluent, outer London areas, and a lower rate than 10.9% might therefore have been expected (Table VII). However, none of the relatives of bipolar patient were cases themselves.

Knowledge about the nature and cause of the patient's condition

Most spouses attributed the patient's difficulties to something external - mental illness (42%), "nerves" (21%), or depression (12.5%). Three spouses felt that the patient had always been "that kind of person" and two could not say what was wrong with the patient. These five were all married to neurotically depressed patients. Three-quarters of the relatives of patients with bipolar affective disorder felt that their spouse was suffering from some form of mental illness, as compared with a quarter of relatives in the other two groups. Husbands were more prone than wives to use vague terms, like "trouble with nerves". The most common cause of the patients' difficulties given by relatives was that "things got too much for them" (42%). One-third of the sample had no idea what caused the patients' difficulties.

Relatives were asked whether they saw the patient or themselves as having any control over the problem. Nearly all the relatives thought that they themselves had little or no influence on the patient's condition, and two-thirds felt that the patient had little or no control over it either. Nevertheless, a small number in each group did think that the patient had some control.

Asked whether they could distinguish normal mood swings in the patient, or if changes in mood always meant that the patient was becoming unwell again, over half the sample (58%) reported that they were able to distinguish changes in mood which were not illness-related. However, among the spouses of unipolar depressives, 62% felt that changes in mood always meant the patient was becoming unwell again.

Services provided, services suggested

Relatives were asked about the amount of general information they had been given regarding the nature of the patient's difficulties, what had caused them, and what the outcome was likely to be.

Over half of the spouses reported that they could not remember having been provided with any information of this kind. Five spouses (21%) said they had received some information, three (12.5%) had received quite a bit, but only two spouses felt that they were given sufficient information to enable them to understand fully the patient's difficulties. The percentage of spouses who reported that they were provided with no information differed between the three patient groups. Thus, just over a third of the relatives of bipolar depressive patients, almost two-thirds of those of unipolar depressives, and three-quarters of those of neurotic depressives reported that they did not receive any information. Men were noticeably less likely to report that they had been provided with information about their spouses' problems.

Nearly all spouses said that they had never been told anything about the kind of behaviour to expect from the patient as a result of the illness, and the two (8%) who were provided with a little information in this regard were relatives of bipolar depressives. Nobody in the entire sample could remember ever having been given any advice on how to deal with patient behaviours they found difficult to cope with.

Half of the relatives interviewed did not feel that they could contact the hospital if they were worried or needed advice on matters relating to the patient. A further 42% felt that they could contact the hospital but had never actually done so. Only two relatives (8%) reported that they had actually contacted somebody at the hospital when they were worried about something. In contrast to this, almost everybody (92%) said that they had no doubts about being able to contact the hospital in times of crisis.

Only three relatives said that they were fully satisfied with the services they had received from the hospital. The remainder were either not satisfied at all with the service the hospital provided, or felt that there was much room for improvement.

The final question put to relatives was what they thought professionals should be providing for them, and what they would find helpful in their present situation. The replies are shown in Table VIII.

Discussion

This study is based on small numbers and its findings must be assessed within that limitation. However, its importance lies in describing the sorts of problems faced by those living with patients suffering from persistent depressive disorders. If the relative of a given person suffering from depression might share the sort of situation experienced by the spouses in our sample, the awareness of the mental health professional should be directed towards that fact. Humane and knowledgeable questioning will then establish details and provide the basis for any intervention necessary for the well-being of the patient and the relative. This being said, we would nevertheless be surprised if some degree of burden is not a commonplace among the relatives of depressive patients, at least where the disorder is of some duration and persistence.

Some of the relatives originally canvassed could not be interviewed because they, the patient, or the consultant withheld permission. This may have happened precisely because of particular difficulties between the patients and their spouses.

The patients selected were deliberately chosen because their illness had started at least two years previously. This means the findings here cannot be generalised to more short-lived and recent illnesses, and that there is no information about how relatives are affected by the onset of illness nor of how they change in their behaviour over time.

Our conclusions must be that relatives *are* affected and *do* bear burdens as a result of the patient's depressive illness. Although they rarely complain, these effects may be far-reaching. The enormous amount of time which relatives spent in the presence of the patients was probably both a cause and a consequence of the notable curtailment of leisure activities. Many spouses objected to this "smothering". Henderson *et al* (1981) pointed out the restricted social networks of those with affective disorders. The current study supports the claim of Nelson *et al* (1970) that this restriction also extends to the patients' spouses.

Marital and sexual relationships were badly affected. It is, of course, possible that marital difficulties may have been involved in the initiation of the depression, but the nature of the changes recorded and their apparent timing must lend some credence to the possibility that they were consequences of the depressive disorder. Spouses took over various roles the patient would normally be expected to carry out, and wives found this particularly difficult. These results confirm those of Collins *et al* (1971), who describe conflict over role functions in couples where the husband was depressed.

Relatives lost the facility of confiding, and commonly took decisions on their own. Their expectations of the relationship were generally reduced and many, particularly women, had a sense of bereavement as a result. There was an increased rate of minor affective disorder among relatives. This could have been due to assortative mating, but the evidence for this has been doubted (Kreitman *et al*, 1970; Merikangas, 1982). It has been claimed that the combination of stressful circumstances and the lack of someone to confide in is particularly detrimental (Brown & Harris, 1978). Our sample of relatives was fairly clear why they were depressed: as one husband said, "her depression is catching".

In contrast to the effects on the marital relationship and the situation at home, performance at work was relatively little affected. In fact, for some relatives, work provided their only break from being with the patient. However, the effect on finances could be very marked, especially where a male patient could no longer function as breadwinner.

The symptoms that relatives most frequently found burdensome were the 'negative' ones, such as worrying, irritability, and nagging. Because they overlapped with normal patterns of behaviour, these were frequently not seen by the relative as arising from the patient's depression. This is similar to findings in the relatives of those with schizophrenia (Creer & Wing, 1974), who complained less frequently; of florid than of negative symptoms. Florid symptoms also cause difficulties, but they are intermittent and less frequent, and the major proportion of the burden occasioned by symptoms seems to come from the negative ones. This may not be appreciated by those responsible for the care of the patient.

Although all groups of relatives were affected, those of bipolar patients were less so. This was partly because most bipolar patients were not disturbed at the time of the interviews, partly because the episodic nature of the condition meant that relatives obtained at least some relief, and partly because the symptoms were more easy to distinguish from ordinary behaviour – it was more obvious that something was wrong. There is no doubt that relatives were upset at times of acute disturbance. It is probable that psychiatrists find it easier to inform and advise the relatives of those with bipolar affective illness.

Female relatives tended to be more affected than males. They experienced an additional burden if they were faced with having to become the chief earner. They tended in any case to have fewer social contacts. Many expressed the strain involved in having to take over untraditional roles. Our findings are tentative, but such gender differences would seem a useful subject for future research.

Relatives' views of the service they received from those caring for the spouse require little additional comment. The main areas of complaint concerned deprivation of information or support, and difficulties over admission.

These findings, however qualified, have implications for services. The management of depression should always be designed to take account of the family setting, and people ought to be involved in decisions about care for their depressed relatives. Relatives could be offered the information and support they lack without major changes in existing services. However, more structured interventions could also be considered, like those used in studies of the families of schizophrenic patients (Falloon *et al*, 1982; Leff *et al*, 1982).

Our results argue for the provision of a service for the relatives of depressed patients on grounds of simple humanity. Such a service is likely to have the additional benefit of improving the lot, and possibly the prognosis, of the patients themselves.

Acknowledgements

Acknowledgements and thanks are due to the consultants and patients of the Maudsley Hospital, without whose co-operation our study would have been impossible. We are indebted to our colleague Brigid MacCarthy for allowing us to adopt the questions developed for the Camberwell High Contact Study for our own research. The study on which this paper is based was in part fulfilment of the requirements of the MPhil (psychology) degrees of the University of London (G.F.).

Neural Substrates of Violent Behaviour

A Preliminary Study with Positron Emission Tomography

NORA D. VOLKOW and LAURENCE TANCREDI

Brain function was evaluated in four psychiatric patients with a history of repetitive purposeless violent behaviour, using EEG, CT scan, and positron emission tomography (PET). Three patients showed spiking activity in left temporal regions, and two showed CT scan abnormalities characterised by generalised cortical atrophy. The PET scans for the four cases showed evidence of blood flow and metabolic abnormalities in the left temporal lobe. Two patients also had derangement in the frontal cortex. The patients showing the largest defects with the PET scans were those whose CT scans were reported as normal. This paper shows the utility of PET in investigating possible brain derangements that could lead to violent behaviour.

The distinction between violence and aggression is an important one. Aggression is a normal physiological behaviour that allows the organism to survive in its environment. Violence, on the other hand, is a form of aggression where the adaptive role has been lost, and which may reflect dysfunctions of the neural mechanisms associated with aggression (Williams, 1969; Yeudall, 1977; Monroe, 1981; Joest, 1983; Krieger, 1985).

Studies of violence have shown that subjects who commit repetitive acts of violence show higher incidence of abnormal brain function as evidenced by neuropsychological tests, electroencephalogram (EEG), and computerised tomography (CT) scan (Yeudall *et al*, 1982; Lorimer, 1972; Williams, 1969; Krieger, 1985). These abnormalities tend to be localised mainly in three brain areas: the frontal cortex, the amygdala, and the temporal cortex. These cerebral regions coincide with the areas implicated in the genesis of aggression in animal studies (Goldstein, 1974; Albert & Walsh, 1984; Mirsky & Harman, 1974).

Positron emission tomography (PET), a new imaging technique that allows direct investigation of brain function (Phelps *et al*, 1982; Volkow *et al*, 1985), may be of help in detecting cerebral abnormalities unrecognised by other imaging or electrophysiological techniques.

In this study we investigated the brain characteristics of four individuals with a history of recurrent violent behaviour, using PET, CT scan and EEG.

Method

We selected four patients from the in-patient psychiatric unit who had had at least three episodes of legal arrest because of violent behaviour. All of the patients were right-handed males and had an additional DSM-III (American Psychiatric Association, 1980) diagnosis for mental disorder. On admission, patients had a full psychiatric, neurological, and physical examination. All subjects had a CT scan with and without contrast, and an EEG performed with and without photic stimulation. All subjects were investigated with PET using ^{15}oxygen-labelled water for determination of cerebral blood flow and ^{18}fluorodeoxyglucose (FDG) for determination of glucose metabolism. The

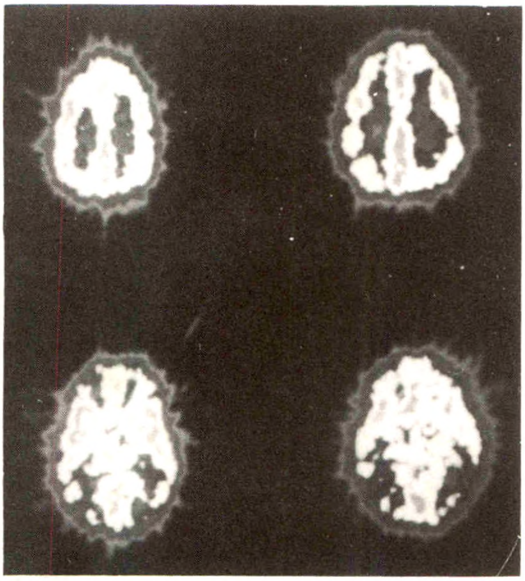

FIG. 1 Typical image for cerebral blood flows in a normal subject. The upper left and right images are at the level of the centrium semiovale; the lower left and right are at the level of the basal ganglia. All the images are axial planes. Note the high level of activity in the prefrontal cortex and the relative symmetry for left and right flow. (Left side of the image corresponds to left hemisphere.)

subjects were tested under baseline conditions (eyes open and ears unplugged). The studies were done using the TOFPET instrument (FWHM 1.2 cm) (Mullani *et al*, 1984). An initial attenuation image was obtained using a ring filled with ^{68}gallium, and a total of 200 million events were collected. The measurement of regional cerebral blood flow (CBF) was obtained after an intravenous bolus injection of 30-35 mCi of ^{15}oxygen-labelled water (Raichle *et al*, 1983). For this image, scanning was started immediately after injection of the label. The images were reconstructed by integrating the radioactivity detected from time of entry of the compound into the brain until peak counting was achieved (30-35). Measurement of glucose metabolism was obtained after an injection of 8-10 mCi of ^{18}FDG (Reivich *et al*, 1982). Scanning was started 40 minutes after injection and was continued for a total of 20 minutes.

PET images were analysed by comparing the left temporal versus the right temporal and the frontal versus the occipital cortex of the three slices centered at the thalamic level. The regions of interest were drawn directly on the PET images and the values obtained were an average of the total number of counts detected for the region in the three slices. Ratios were plotted both for the FDG and for CBF.

As a reference, a similar procedure was done in the CBF images obtained from four normal volunteers matched for age, sex, and handedness.

Patients

Case 1 was a 30-year-old white male, in hospital because of suicidal and homicidal ideation. The patient had a diagnosis of bipolar affective disorder and post-traumatic stress disorder. At the age of 25 he suffered a brain concussion, with loss of consciousness. Since then he had abused alcohol regularly. During intoxication he became extremely violent and had several incidents of physical assault, including homicide. The patient did not report guilt or repentance for his actions. He was treated unsuccessfully with various antidepressants, minor tranquillisers, and neuroleptics. The family history was positive for alcoholism in both parents, and for depression in the father.

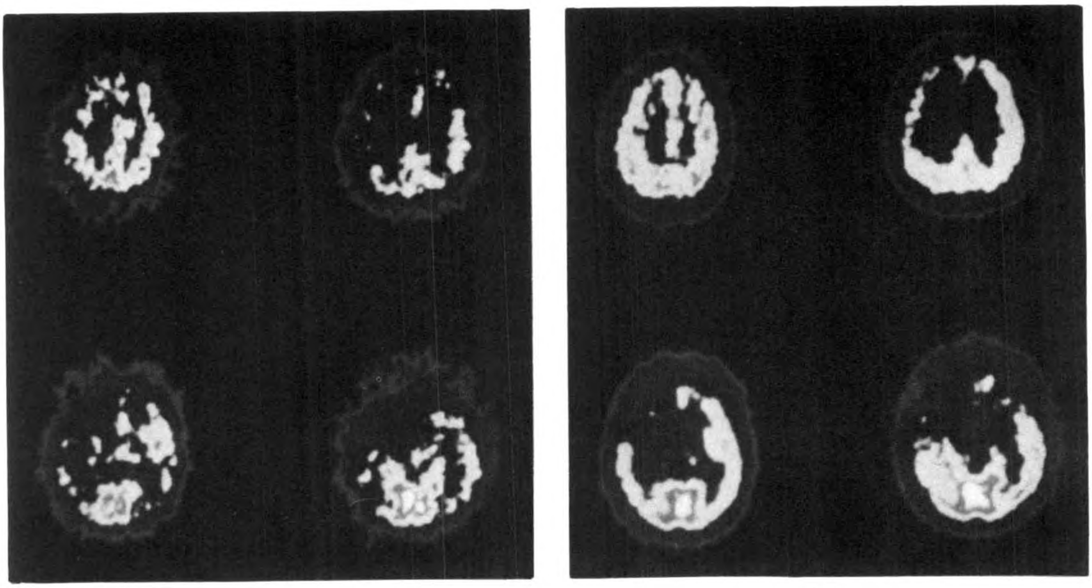
Case 2 was a 45-year-old black male in hospital for agitation and violent behaviour. Because of similar previous episodes, the patient had been misdiagnosed as chronic schizophrenic. He had been in prison for repeated incidents of violent, impulsive behaviour, including physical assault, arson, and rape of his sister. He did not seem to have an understanding of the ethical implications of his behaviour. There was no psychiatric history in the family. While in hospital, the patient's violent behaviour decreased with doses of neuroleptics.

Case 3 was a 21-year-old white man in hospital after a suicide attempt, with a diagnosis of borderline personality. At the age of 15 the patient began to exhibit outbursts of violent behaviour. During these episodes he experienced intense rage and lost control of his behaviour, and afterwards had no recall of the event. He also had a history of impulsive suicide attempts; by hanging and by drug overdose. The patient had a positive history of alcohol and drug abuse, mainly marijuana and phenobarbital. The family history was positive for paranoid schizophrenia and epilepsy in two of his three siblings. The patient was treated with Tegretol, with some resolution of the impulsive destructive behaviour.

Case 4 was a 39-year-old white male in hospital because of outbursts of uncontrollable violent behaviour. The patient had a past history of post-traumatic disorder and alcohol abuse. Since his return from Vietnam in 1968 he had had several episodes of uncontrollable violent attacks while intoxicated with alcohol. On one occasion, he shot a gun at his father; on another occasion he attempted to strangle a priest. He also made several suicide attempts. At the age of 30 the patient had a three-year history of generalised motor seizures, which were treated with Dilantin. He had been treated unsuccessfully with minor tranquillisers and antidepressants. There was a psychiatric history in the family. While in the hospital, the patient was treated with clonazepam, with resolution of the panic attacks and violent behaviour.

Results

Table I gives the left/right (L/R) and frontal/occipital (F/O) ratios for the FDG and CBF images of the patients and for the CBF images of the control subjects. All of the controls showed higher L/R values than the patients. Except for one of the control subjects, they also showed higher F/O CBF ratios than the patients. Of the patients, cases 1 and 2 had the lowest L/R and F/O ratios both for FDG and CBF. Figure 1 shows a typical image for CBF of a normal subject.



(a) (b)

FIG. 2 Case 1: images for (a) CBF and (b) FDG. Note the severe disruption in the frontal cortex, and left temporal area. Planes are similar to those of Fig. 1.

In case 1, the EEG revealed left anterior temporal sharp and slow wave activity, suggestive of an irritative lesion with epileptogenic potential. The CAT scan was reported as normal. The PET scan showed a defect of brain metabolism and blood flow on the left hemisphere, which was more accentuated for the left temporal cortex and frontal area (Fig. 2).

In case 2, the EEG and the CT scan were reported as negative. The PET scan showed decreased metabolism and blood flow on the left temporal cortex and the frontal cortex (Fig. 3).

In case 3, the EEG reported brief runs of left temporal sharp slowing consistent with an irritative lesion. The CT scan reported accentuated cortical atrophy. The PET scan showed a slight decrease in cerebral blood flow on the left temporal cortex (Fig. 4).

In case 4, the EEG reported left temporal slowing and sharp waves as well as excessive delta wave activity more marked for the posterior regions, suggestive of mild diffused disturbance of cerebral function. The CT scan showed atrophic changes out of proportion for age. The PET scan showed a mild decrease of blood flow for the left temporal area. The right temporal region showed an area of increased CBF (Fig 5).

Discussion

These four patients had in common a history of repetitive purposeless violent behaviour. Cases 1 and 4 showed violent behaviour mainly under the influence of alcohol. All of these patients showed temporal cortex asymmetry, with the left showing lower blood flow and metabolism than the right. Cases 1 and 2 also showed severe flow and metabolism disruption on the frontal cortex. Cases 1 and 2 appeared to show no remorse for their actions, whereas cases 3 and 4 regretted their violent behaviour after its occurrence. Cases 1 and 2 showed larger areas of defect on metabolism and CBF than cases 3 and 4, yet their CT scans were normal, whereas cases 3 and 4 showed minimal metabolic and CBF dysfunction and their CT scans revealed marked cortical atrophy. The EEGs of cases 1, 3 and 4 showed spiking activity in left temporal areas.

These cases illustrate the complexity of trying to understand cerebral derangements associated with violent behaviour. Rather than a particular focal brain lesion, these patients showed widespread defects in cerebral function, as evidenced by PET; all revealed evidence of left temporal dysfunction. These regional defects were not detected with the CT scan, which, if abnormal, showed only cortical diffuse atrophy. Cerebral dysfunction in this group of violent individuals, shown by the higher sensitivity of PET over CT scan, suggests that organic brain dysfunction in violent offenders may be more frequent than was previously recognised.

Analysis of the violent act is of importance in understanding possible neural system implication in

its occurrence. At least three basic syndromes associated with neurological impairments have been described for the occurrence of violent behaviour. Firstly, defects in the prefrontal area, which is implicated in higher cognitive functions like consciousness and abstraction (Luria, 1966), could facilitate the occurrence of violent behaviour because of inability to understand concepts such as right or wrong or to appraise the consequences of the violent act. Secondly, abnormalities in the limbic areas (including medial temporal cortex), which are responsible for generation of affects and emotions, could elicit feelings that arise *in vacuo* (that is, independent of an evoking condition) (Blumer *et al*, 1974). This type of patient will tend to show random outbursts of rage and violence (Wieser, 1983), with very poor impulse control (Mungas, 1983). This subtype of violent individual appears to have a higher incidence of EEG abnormalities. Thirdly, abnormalities in the association areas of the brain which lead to derangements in perception would evoke assaultive behaviour when a stimulus is perceived as threating (Valzelli, 1981).

It is important to emphasise that we do not attribute the violent behaviour of these cases solely to brain abnormalities, but rather that the occurrence of the violent outbursts was facilitated by the cerebral dysfunction. Most of the violent behaviour seen in patients probably represents complex interactions between various neural systems, neurotransmitters, hormones, environmental stimulus, and learned responses (Mednick, 1982).

New imaging techniques such as PET allow us to detect cerebral pathology which was henceforth unrecognised by the EEG and the CT scan. PET, being designed to investigate cerebral function, is a very promising tool to help evaluate cerebral derangements in individuals with violent behaviour, and hence may help in the design of better preventive and therapeutic interventions.

A Ten-Year Follow-Up of Men Discharged from Grendon Prison

GRAHAM ROBERTSON and JOHN GUNN

A ten-year follow-up on the criminal records of men discharged from Grendon Prison was carried out. These records were compared with those of a matched control group, and no differences were found regarding frequency or severity of post-discharge convictions. The validity of this exercise is questioned, and several case histories presented. An examination of subsequent offending within the Grendon group suggests that for some men, the better motivated and more intelligent, exposure to the Grendon regime may have contributed to a change in their criminal behaviour.

Grendon prison is an important psychotherapeutic unit within the prison system of England and Wales. It was originally proposed before the Second World War in a Home Office report (East & Hubert, 1939) and opened in July 1962. Its history and its therapeutic system have been described previously (Gunn *et al*, 1978), and its operation has recently been reviewed by a Home Office working party (Home Office, 1985). The regime in Grendon is a modified therapeutic community. It is not a hospital as defined by the Mental Health Act, thus it does not take offenders/patients given hospital orders under the Act. Offenders are not accepted direct from courts, but only after selection and preliminary investigation by medical officers in the prison service. Such prisoners must not be suffering from psychotic illness, must be willing to co-operate in the regime, and can apply to be returned to an 'ordinary' location if they wish. For most of its life the prison has been under the directorship of a medical director, but at time of writing and for the last few years has had a lay governor as its head.

Background

In the early 1970s, the Home Office commissioned the Forensic Psychiatry Section of the Institute of Psychiatry to evaluate the regime and its effects. The original study population comprised the intake to Grendon over a 12-month period, numbering 107 men. Most were in their middle-to-late twenties and had long criminal records. Many men had no home at all to return to after release, and there was no indication that the Grendon authorities were selecting men with a good prognosis in terms of their chances of being reconvicted.

In the original follow-up study 61 men were involved, and each was matched to a man in another prison who was not receiving psychiatric treatment. The Parole Index was used for matching. This is a systematic collection of demographic data on all convicted prisoners serving sentences of 18 months or more. Consequently, we were able to match on those variables of most importance in criminological prediction. Details are provided in Gunn *et al* (1978). Although well matched, the two groups also differed in some important respects. For example, when compared on their attitudes to treatment and to psychiatry, 88% of the Grendon men expressed some or a considerable desire for psychiatric help, compared with only 46% of men in the control group.

The ten-year follow-up study

The purpose of the present paper is to report the results of a ten-year criminological follow-up of the cohort previously studied. In our original report, we argued that reconviction rates were an inappropriate measure of Grendon's performance. Statistically, the variance contributing to reconviction in a given period is enormous, involving as it does the totality of the man's previous experiences, as well as huge error or random components, not the least of which is the difference between committing offences and being caught and convicted for those offences. It was argued that a fixed and limited period of time spent in prison X as opposed to prison Y constituted a tiny fraction of the variance which might be held to contribute to the criterion measure of reconviction, and that the measurement of its contribution was confounded by lack of control over these more potent contaminating variables.

Nonetheless, we were interested in finding out what had happened to the men we had interviewed in Grendon and to those men who comprised the control group for the Grendon cohort. Earlier efforts to keep in touch with these men when they left prison had proved very difficult. Six months after release, the response rate to the questionnaires we sent to them had fallen to 41%, and by 12 months the response rate was in single figures. We reluctantly therefore had to fall back on official records and, predominantly, criminal records.

Method

The criminal records of all men in the follow-up groups were obtained from the Criminal Records Office. The National Health Service Central Register supplied information about those men who had died, including the nature of any deaths that had occurred. These data were added to the information available from the original study, enabling post-discharge criminal variables to be correlated with the information we had obtained ten years earlier.

Results

The majority of men in both the Grendon and control groups had been reconvicted at some point during that ten-year period (92% and 85% respectively, $\chi^2=1.37$, d.f. 1, NS). In that time the Grendon group had made, on average, 5.3 appearances in court and the control group 4.5 ($t=0.80$, NS). Offences of serious violence (and we have included robbery in this category) were committed by 20% of the Grendon group and 17% of the control group. Between 60% and 70% of both samples had received a custodial sentence, and in this category we have included two men in the control group who had been sent to a special hospital under a hospital order.

The types of offence covered the full range of criminal behaviour. As would be expected, the most serious types of crime were rare (homicide, rape, grevious bodily harm and arson), and the only category of offence of numerical significance concerned acquisitive offending. In the Grendon group, theft represented the only type of crime committed by a majority of men. This was true also for the control group. Convictions for drug offences were significantly more common among the Grendon men, 13 (22%) of whom had received such a conviction compared with only one man (2%) in the control sample ($\chi^2=11.43$, d.f. 1, $P<0.001$). It is not surprising to find the two groups differing in this respect on follow-up, as despite exhaustive efforts to match these groups in the original study, the Grendon sample contained significantly more men with a known history of drug abuse prior to their participation in the study (19% of the Grendon men had convictions for drug-taking compared with 3% in the control group; $\chi^2=6.82$, $P<0.01$). The removal of all drug offenders from further analysis made no difference to the other results.

Post-discharge offending within the Grendon sample

As our main interest here is in Grendon and in the association between changes which had taken place there and post-release behaviour, only the Grendon population has been used for the remainder of the analysis. We examined the data to determine what variables were associated with recorded post-discharge criminality. For this purpose, two criteria were used: (a) the number of subsequent court appearances made (as a reflection of frequency of offending) and (b) the amount of imprisonment awarded by courts in that period (as a reflection of seriousness of re-offending).

TABLE I
Variables which correlated most highly with length of subsequent imprisonment in the Grendon sample

Variable	*r*	*P*	*n*
Criminal profile			
Our rating of violence	0.28	0.015	60
Our rating of drink-related offending	0.32	0.007	60
Personality characteristics			
History of disturbed personal relationships	0.29	0.012	60
Impulsiveness	0.29	0.012	60
Mental health assessment			
Alcohol problem	0.27	0.018	58
Depression	−0.31	0.009	58
Self-ratings			
Self-esteem	−0.25	0.039	51
Response to item 2 on the AC scale, "I like mixing with criminals"	−0.30	0.009	60

Table I presents the variables found to be associated with our measure of the seriousness of subsequent offending. The list has been restricted to items which correlated at greater than the $P=0.05$ level with the criterion variable. The variables in the table can be grouped into four categories: (a) alcohol abuse; (b) impulsiveness/violence; (c) low scores on the assessment of depression at mental state examination; and (d) low self-esteem. Item 2 of the Attitude to Criminality (AC) scale states, "I like mixing with criminals", and was negatively correlated with extent of subsequent imprisonment (those men who said they liked mixing with criminals were likely to have spent less time in prison). This is a rather unexpected result, but it may be that to assert a dislike for mixing with criminals is positively linked to self-esteem.

Table II presents the most statistically significant correlates of the number of court appearances made following discharge from Grendon. As with our measure of seriousness of reconviction, various indices of drinking behaviour were found to correlate significantly with the number of further convictions recorded. In the case of the frequency of post-discharge court appearances, variables such as vagrancy and low drive (defined in the study as lack of normal ambition and purpose) were associated with the criterion variable, rather than the violence and impulsiveness which correlated with length of subsequent imprisonment. At interview, we had assessed each man's propensity to lie,

TABLE II

Variables correlated highly with number of post-discharge court appearances in the Grendon sample

Variable	*r*	*P*	*n*
Personality characteristics			
Lying	0.32	0.006	60
Vagrancy	0.32	0.006	60

Previous criminality			
Total number of pre-Grendon court appearances	0.43	0.0001	60
Number of previous convictions for drink offences	0.28	0.016	60

and this rating was found to be associated with number of subsequent reconvictions. The Lie scale of the Minnesota Multiphasic Personality Inventory (MMPI) was also linked with reconviction, but to a smaller extent ($r = 0.27$, $P < 0.03$). One of the most statistically significant findings was the relationship between IQ and further convictions. The test used to measure intelligence, the AH4, is divided into two parts. The first part consists of verbal and numerical items, which in part reflect the educational level of the individuals completing the tests. The second part is much less dependent on education, consisting as it does of items requiring the manipulation of spatial material, and it is this part of the AH4 which correlates most highly with our criterion variable ($r = -0.48$). Attitude to psychiatry, as expressed on a rating scale, was also linked with frequency of reconviction, poor motivation being associated with reconvictions. It is noteworthy that mental state variables, including changes in Grendon, were not associated with post-discharge offending.

Relationship between attitudes towards psychiatric treatment and post-discharge criminality

In an earlier report (Robertson, 1974), it was stated that Grendon staff believed there to be a relationship between motivation and 'doing well' after release. In particular, it was supposed that men who were more motivated when they came to Grendon did well as a group; that those not well motivated did not do well; and that those who, although poorly motivated on arrival, improved in this respect did best of all.

In order to examine the first of these hypotheses, namely that men who came to Grendon with better motivation did better than those who were less well disposed to psychiatric treatment, the population was broken down into three groups on the basis of their Attitude to Psychiatry (AP) scale scores. Results are presented in Table III. Although not distinguished from one another in terms of the number of pre-Grendon court appearances made, nor indeed on any other of the major criminal variables, such as age at first conviction ($P < 0.71$) or the extent of their juvenile offending ($P < 0.83$), the group of men who had expressed a low opinion of psychiatry had made significantly more court appearances in the period following their discharge. This was supported by a related finding. In the original study, prison officers and other group leaders were asked to rate motivation for each man on a four-point scale; and the authors carried out a similar exercise after interviewing each man. Both sets of ratings correlated with frequency of court appearance after discharge, but not with subsequent length of sentences awarded by courts.

The hypothesis that men whose motivation had improved during their stay in Grendon would be those who did particularly well once they were released was tested by dividing the population on the basis of improvement in AP scale scores, but this produced no significant differences between groups as regards our outcome measures.

Case histories

The present report has the advantage over many reconviction studies of being able to consider behaviour over a long period of time. However, as the following three histories demonstrate, even with a ten-year follow-up period, official records remain an extremely crude and dubious measure of offending behaviour. In their separate ways, they also bring into question the issue of whether events which take place years after discharge from an institution can properly be linked to events within that establishment.

The first case was a man in his late thirties when admitted to Grendon, who was serving a long sentence for armed robbery. Being older than the majority of inmates, he felt that he had been of use to the younger men on his wing, and that for the first time in his life he had had something to contribute to others. He was realistic about his ability to go straight when he was released, and indeed, once discharged from Grendon, he received his first conviction within a few months, for stealing. This was followed some years later by convictions for burglary, for drunkenness, and for drug offences, making a total of four convictions altogether. None of these resulted in his being sent to prison, and in comparison with his previous record they represented a considerable improvement in his behaviour. Shortly before the follow-up period was due to elapse, he was involved in a drunken brawl which resulted in the death of the man

TABLE III

Criminal and other characteristics of the Grendon sample divided on the basis of their Attitude to Psychiatry scale scores

he had fought with. Medical examination in his remand prison showed him to be terminally ill, and his prosecution was not proceeded with. He does not, therefore, figure as a homicide offender in our statistics. But even suppose that these exceptional circumstances had not pertained, and that he had been charged and found guilty of murder: what would it have meant? Ten years after he left Grendon he was involved in a drunken fight which culminated in tragedy. By that time the man was almost 50 years old and had spent a great deal of his life in all manner of institutions. In such circumstances, it is not possible or reasonable to hold Grendon attributable for that piece of behaviour.

The second inmate was a man in his mid-twenties when we first interviewed him. He had made his first court appearance at the age of 11 and had subsequently been convicted many times. On release from Grendon, he lived in a hostel and quickly returned to drug-taking and petty thieving – but was not caught. Within a year he had met a girl and they had settled down together. In the context of this relationship, and unusually for him, he found himself a job which offered security and prospects of promotion and which lasted some years. The break-up of his relationship with his girlfriend precipitated a general deterioration in his behaviour and ultimately led to a conviction for theft and to psychiatric treatment on an out-patient basis. The potent variable in determining his early success and later disintegration was an event over which Grendon had no control and for which it was not responsible.

The third man highlights the problems inherent in relying on conviction statistics alone. In his mid-twenties, his criminal career had started in the juvenile court and he had a considerable record by the time of his admission to Grendon. He had requested a transfer to Grendon because he wanted to do something about feelings of depression. When we conducted our final interview with him he said that he had benefited from his experience in Grendon, had come to terms with what he called his inferiority complex, and felt the place had made him more confident in himself. At the same time, he said he would probably return to stealing and indeed, once out, did so. But we know this only because of his report to us; he was not convicted for these offences. When his ten-year follow-up period ended he had a completely clean record. Judged by his former criminal record this event alone might have been hailed as little short of miraculous. Several months after the follow-up time had elapsed, he was convicted of possessing firearms and received a long prison sentence. By his own account he had continued to steal after leaving Grendon, and, rather than representing an improvement in his behaviour with regard to crime, his clean record in the period following discharge probably represented a marked improvement in his ability to avoid arrest. As it stands, a dismal pre-Grendon record contrasts with a completely clean sheet. Once again, the random or error variance in the equation makes statistical examination of a treatment effect totally inappropriate.

Discussion

Men who came to Grendon vary in their motivation for treatment and in their intelligence. The figures presented in Table III suggest the possibility that there is an interaction effect between motivation, intelligence, and Grendon, so that time spent there by the more intelligent and better motivated men may have made some difference to their later behaviour. Such a result would not be too surprising, given that the help offered in Grendon (group therapy) is dependent on the ability and willingness of the participants to talk. If this is indeed so, Grendon's role is best regarded as that of a catalyst, acting by giving men who want to change the opportunity of spending their time in prison constructively. We believe this to be a realistic description of what goes on there. To view the prison as 'treatment', analagous to the criterion variable in a physical experiment, is inappropriate and misleading.

Of more general criminological interest is the distinction to be made between the seriousness and frequency of reconvictions. These were found to have different correlates. For both measures, drinking behaviour was associated with poor outcome. But in the case of seriousness of reconviction, an association was also evident with violence and with various associated personality attributes such as impulsiveness and irritability ($r=0.26$, $P<0.023$). On the other hand, frequency of court appearances was associated with vagrancy, low drive, low intelligence, low self-esteem, and measures of motivation.

Conclusions

How should Grendon be assessed? It shares with all other penal establishments the aims of the prison service. Rule 1 of the Prison Rules (Homes Office, 1964) states that the aim is "To hold (securely) those people admitted to custody and to encourage and assist them to lead a good and useful life". Measured in these terms, Grendon has proved to be a success. In its 23 years of operation, only one man has ever escaped from it. Our earlier study described the efforts made in Grendon to encourage its inmates to lead a "good and useful life". For many men in the prison system, the main characteristic of a sentence is that it represents wasted time. Life on the outside ceases to exist, but the enforced isolation from normal society is not given over to contemplation and self-improvement but rather to tedium, discontent and further alienation. Because Grendon makes an effort to encourage inmates to change, it has tended to be compared with other prisons on whether or not it performs better in regard to the behaviour of its 'graduates'. The question which might better be asked is why all other prisons do not do as much as Grendon in this respect.

The question, "Does Grendon work?" is simplistic and naïve. Grendon is an institution which accepts individuals of widely differing opinions, motivation, and ability. For those who go there, it provides an opportunity to examine past behaviour and current problems. There is a fairly strong indication from this investigation that some such men, the more intelligent and positively motivated, may indeed use their experience to alter their lifestyles. But common sense would suggest that much more attention should be given to care in the community for these men if the potential for change is to be capitalised on.

Ten years after our original investigation of the prison, we remain convinced that it is a paradigm for good prison management, that it presents for all its inmates the opportunity not to waste time during their incarceration and that, for some, it may represent a watershed in their lives.

Acknowledgements

We are grateful to the Home Office for allowing us to carry out this study and for providing helpful comments, although it must be pointed out that it did not commission the work. We thank Susanne Dell, Pamela Taylor, David Farrington and Maureen Bartholomew for their interest and help.

A Ten-Year Follow-Up Study of Southampton Opiate Addicts

J. GUY EDWARDS and ANN GOLDIE

A ten-year follow-up study of 74 opiate (most heroin) addicts referred to the Drug Dependence Clinic in Southampton showed that overall, little use was made of the treatment facilities available. Half of the patients on whom we were able to obtain follow-up data appeared to be no longer abusing drugs. An appreciable number of subjects had committed offences prior to abusing drugs and a large proportion offended during the follow-up period, adding support to the view that most addicts are not driven to crime because they are unable to obtain the help they need. The death rate of 15% is that expected in a long-term follow-up study. The results suggest that the natural history of many heroin addicts is uninfluenced by therapeutic intervention.

A Drug Dependence Clinic for Southampton and South West Hampshire was established in 1968 on the recommendation contained in the Second Report of the Inter-Departmental Committee on Drug Addiction. The functions of the clinic are described, together with the results of a ten-year follow-up study of 74 opiate addicts referred between September 1969 and February 1973. Relatively few addicts have been followed up over such a long period, and even fewer studies of opiate addicts have been carried out in provincial cities.

Size of the problem

The prevalence of drug abuse in the Southampton District is not known, but during the period of study the Psychiatric Case Register identified 80 patients given the diagnosis Drug Dependency, Morphine Type (ICD 304.0). This is an underestimate of the problem, as only data on patients referred to the service are recorded in the register. It is likely that the cohort described represented a significant proportion of the total population of Southampton opiate addicts during the early 1970s.

The service

Patients were referred by their GPs, other medical colleagues, social services, probation and after-care departments, the courts, solicitors and voluntary organisations. Most patients were seen as out-patients within a week, or within a day if necessary. Those thought to be dependent on opiates were offered immediate admission to hospital for withdrawal from drugs or to decide whether 'maintenance treatment' was indicated.

Those who refused rapid withdrawal had their drugs withdrawn gradually in the clinic, while a minority of patients, in whom all attempts at persuasion to abandon the drug habit (including imprisonment) had failed, were given maintenance treatment. Such patients attended the clinic daily, although some who did not live near were allowed to collect their drugs from a local chemist. In exceptional cases, patients who were unemployed or who were looking after their families while their spouses worked were given a week's supply of drugs.

Patients who had previously been maintained on diamorphine (heroin) were weaned off this and methadone, initially given intramuscularly and later orally, was substituted. Long-drawn-out arguments over the doses required were avoided, and instead patients were urged to participate in more constructive treatment. They were persuaded to accept rehabilitation in one of the units that have been established throughout the UK, although most who agreed to be rehabilitated were referred to Alpha House, a unit modelled along the lines of the Synanon, Daytop, and Phoenix House experiments in the USA. Addicts referred by the courts or solicitors were assessed by the staff at Alpha House, and if it was thought that they would participate in the rehabilitation programme it was recommended that they be remanded on bail for a 4–6 week trial period in the unit. If this was successful, it was requested that they be allowed to continue treatment under Section 3 of the Powers of the Criminal Court Act, 1973 (formerly Section 4 of the Criminal Justice Act, 1948). The court was also advised that those who failed to co-operate or left against advice should be brought back before the court and dealt with in any other way thought appropriate.

A Drug Abuse Advisory Service was established during the early 1970s to help those who were not prepared to take advantage of these facilities, and to provide advice for the families of drug abusers. This later became the Southampton Inter-Professional Drugs Liaison Committee. It provided the expertise of a social worker; probation officer; community psychiatric nurse; voluntary workers, including representatives from the Samaritans and Nightline (formerly run by Southampton University students, but later discontinued); a solicitor with experience of criminal law (representing the Law Society); a senior police officer; staff from the local authority's departments of education and health education; and a consultant psychiatrist (JGE). A telephone was installed and manned 24 hours a day by Nightline members. The telephone number, identified as a means of obtaining advice anonymously on problems related to drugs, and with no obvious connection with the 'establishment', was widely publicised for use by anyone in the district. Much advice was also given to general practitioners, casualty officers and others in their dealings with individual cases, while an informal telephone call was made to GPs when it was learnt that they were prescribing drugs of abuse, albeit in good faith.

Method

Patients

The cohort studied comprised 53 men (72%) and 21 women (28%). Their ages ranged from 16 to 35 years, with a mean of 21. The majority (92%) were in their late teens or early twenties. All but two patients were British. A large majority (97%) came from social classes III–V. At least four dropped out from school before the age of 16; only five received higher education. The majority of subjects (70%) were single, while a large proportion of those who had been married were separated. Most patients (88%) had unstable work records, having been sacked from several jobs or having had long periods of unemployment. Just over half (52%) lived at home with their parents, while the others lived with a spouse or cohabitee or lived alone. At least 18 patients (24%) had a family history of mental illness, nine (12%) of drug or alcohol abuse and eight (11%) of conflict with the law; some had a family history of more than one of these. At least 12 (16%) had a significant period of separation from their parents during early life, while at least 18 (24%) came from broken homes.

When first seen, the patients had been abusing drugs for periods ranging from two months to more than ten years. Only eight subjects (11%) had abused drugs for less than a year, while four (5%) had taken drugs for more than ten years. Practically all of the patients were poly-drug abusers. Fifty-nine (80%) had come into conflict with the law, at least eight of these prior to abusing drugs. Collectively they had committed 129 offences, mainly illegal possession of drugs, theft, and breaking and entering chemists' and other properties. They had been dealt with by the courts in various ways, including probation, treatment under sections of the Mental Health Act, and imprisonment.

Follow-up

Follow-up data were obtained from case records, and the patients were sent out-patient appointments. Visits were made to the last known address of those who did not turn up, and, if they had moved, attempts were made to trace them at their new addresses. Data were obtained from GPs, probation officers, Alpha House, other treatment centres, prisons and the Home Office files. Only 15 patients (20%) could be traced in person, so much reliance had to be placed on these other sources. Information gleaned from other drug abusers was not used as it was thought to be unreliable. Data suitable for analysis, although not always complete, were obtained on 64 patients (86% of the original cohort). Of these, 47 (73%) were men and 17 (27%) were women. The sex ratio is similar to that of the original cohort, but there is a bias in the age distribution, with a larger proportion of younger women among those followed up.

Results

Use of service

Sixteen patients (22%) received methadone 'maintenance treatment' during the follow-up period. Forty-one (55%) had been admitted to hospital, one patient as many as ten times. The total time spent in hospital (for all admissions) ranged from one day to 200 days, with a mean of 26 days. The average length of stay per admission was 11 days. At least nine patients had been admitted to hospital elsewhere, mainly in London, for periods ranging from 5 to 120 days. The more prolonged stays were for psychiatric illnesses (especially schizophrenia), which were diagnosed in a small minority. Four patients were admitted to hospital under Section 29 and four under Section 25 of the Mental Health Act 1959; all others were admitted informally. Twenty-nine patients (39%) were referred to Alpha House. Six were referred more than once, making a total of 37 referrals. The lengths of stay ranged from one day to two years. Four of the patients had been referred to other rehabilitation units.

Little use was made of the advisory service. Between December 1973 and March 1975 only eight telephone calls were received. Three of these were from students requesting information for sociological projects, one was from a woman asking for information concerning possible interactions between phenelzine and her oral contraceptive and one was a wrong number. Only three calls led to advice being offered on the telephone and in no case was this urgent.

Outcome of treatment

The outcome was assessed in the case of the 64 patients on whom we had follow-up data. Of the original 51 single patients, at least 19 (37%) had married, while of the 11 who were originally married, six (56%) had separated or been divorced. One of these had been divorced and remarried. More than half of the subjects (57%) were working full-time or were housewives, and another 10% were doing temporary or part-time work. A quarter of the patients lived with their spouses, while others lived with their parents, cohabitees or friends. None was homeless.

Forty-three subjects (58% of the original cohort of 74) had committed offences during the follow-up period. Of the 32 men who offended, six had previously been in trouble with the law; 10 of the 11 women who offended also had a history of previous conflict with the law. The main offences were illegal possession of drugs, obtaining drugs by deception, theft, and breaking and entering. These were dealt with by the courts in various ways, including probation in the case of 30 patients (41%) and prison in the case of 19 (26%).

Of the 64 on whom we obtained follow-up data, 32 (50%) claimed or were said to be no longer using drugs, while six (9%) were receiving maintenance treatment with methadone. We noted from the Home Office files that four (5%) of the original 74 addicts were in prison and 11 (15%) were dead.

Patients who appeared to be off drugs were more likely to have been living with their parents or spouses when first seen 10 years earlier ($\chi^2 = 10.540$, 1 d.f., $P<0.01$). There was no significant relationship between apparent abstinence and sex of patient, duration of drug abuse when first referred (five years or less versus more than five years), the provision of maintenance treatment, or whether the patients had remained at Alpha House for a week or longer during the follow-up period.

Discussion

For more than a decade, patients referred to the Drug Dependence Clinic in Southampton have been managed in much the same way as is currently recommended by the Medical Working Group on Drug Dependence of the Department of Health and Social Security. While it is not possible to draw general conclusions from the results of a single study carried out more than a decade ago in a city that could have an atypical drug-dependence problem, a measure of the outcome goes some way towards assessing the effectiveness of this management policy, adds to the sparse literature on the natural history of opiate addiction, and provides results with which those from other treatment programmes can be compared.

Proponents of our treatment have noted that every possible opportunity for help has been provided, and believe that it is not the fault of the service if addicts choose not to avail themselves of these. Critics, on the other hand, have argued that the policy is too rigid, and that insisting on addicts being admitted before providing maintenance treatment is unnecessary. Yet some youngsters who claimed they were addicted have been shown as in-patients not to be dependent on drugs. Had their claim been accepted and drugs prescribed, a non-addicted subject could easily have been given drugs to abuse or sell. In-patient assessment has also shown that maintenance doses of drugs smaller than those demanded usually suffice.

In the field of drug addiction one cannot win. If the treatment offered is not accepted, it is alleged that we are doing too little. If drugs are not readily prescribed, we are made the scapegoats for the problems that addicts bring upon themselves in their attempts to finance their illegal supplies. On the other hand, if we prescribe too readily, it is suggested that we are running clinics for 'kicks' and adding to the black market supply. No compromise on all these difficulties satisfies all people.

Research in this field is fraught with methodological hazards. There are difficulties in diagnosing dependence, difficulties in tracing patients, and difficulties in determining what is a good or bad outcome. Some believe that a good outcome is purely the abandonment of a drug habit; they may overlook the fact that the old addiction has been replaced by a new one, such as dependence on alcohol. Others place the emphasis on social adjustment or maturation of the personality. To a large extent, assessment of outcome is a value judgement that varies from individual to individual and from one professional group to another. Due to lack of financial and manpower resources, our measures of outcome were limited to the use of drugs, employment status, antisocial behaviour, and death.

Overall, little use was made of the service. Many patients did not keep their appointments and only turned up at a time of crisis or when in trouble with the law – sometimes hoping that this would be looked on favourably by the court. Even when addicts initially appeared motivated to abandon their drug habits, interviews often ended with a request for drugs. Not infrequently addicts agreed to admission but did not turn up, while a large proportion of those who did come into hospital discharged themselves against advice. Addicts often agreed to gradual withdrawal from drugs as out-patients but when steps were taken to decrease the dose claimed they were 'not ready'. Many patients were referred to Alpha House but they rarely remained there for long. Little use was made of the Drugs Advisory Service, even though there was no way in which it could have been seen as being associated with the 'establishment'.

In spite of this, the proportion of patients who at follow-up appeared to be no longer using drugs (50%) compares favourably with the results of other studies, in which the proportion of patients not known to be using drugs ranged from 16–45% over follow-up periods of 2–12 years (Bewley & Ben-Arie, 1968; Bewley *et al*, 1968; Zacune *et al*, 1969; Stimson & Ogborn, 1970; Boyd *et al*, 1971; Hitchins *et al*, 1971; Chapple *et al*, 1972; d'Orban, 1973; Ogborn & Stimson, 1975; Stimson *et al*, 1978; Wille, 1981; Cottrell *et al*, 1985). The high employment rate in those on whom we have follow-up data also compares favourably with the results of other follow-up studies, that show employment rates ranging from 21–70% over 1–7 year periods (Zacune *et al*, 1969; Stimson & Ogborne, 1970; Hitchins *et al*, 1971; Stimson *et al*, 1978; Oppenheimer *et al*, 1979; Hartnoll *et al*, 1980). These results subtract from the public image that all addicts end up as unemployed layabouts. The proportion of subjects that got married suggests a shift towards stability, but there is a high marriage rate within the age range of our patients, and the proportion of broken marriages has to be seen in relation to the high rate of marital breakdown in Britain as a whole.

The relationship between drug abuse and crime is complex. Drug abuse may be part and parcel of the chaotic lifestyle of antisocial personalities, while addicts may offend to obtain money for drugs. They often claim that they have been forced into crime by being refused drugs at treatment centres. Our results show that an appreciable number of subjects had committed offences prior to abusing drugs and 58% of them offended during their follow-up period. This is in keeping with the results of previous research, which has shown a higher rate of conviction before starting to abuse drugs than after starting (Kosviner *et al*, 1968; James & d'Orban, 1970; Stimson & Ogborn, 1970; Boyd *et al*, 1971; d'Orban, 1973), and a failure to reduce the rate of offending by prescribing methadone (Hitchins *et al*, 1971; Blumberg, 1976; Gordon, 1978), although in some studies a short follow-up period was compared with a long drug-taking career prior to attending the clinic. It appears, therefore, that addicts are not driven to crime because they are not given drugs, but are more often criminals to begin with.

A death rate of 15% is expected in a long-term follow-up study of this kind, previous studies having shown rates of 2–15.7% over follow-up periods of 1–11 years (James, 1967; Bewley & Ben-Arie, 1968; Bewley *et al*, 1968; Hitchins *et al*, 1971; Chapple *et al*, 1972; d'Orban, 1973; Ogborn & Stimson, 1975; Thorley *et al*, 1977; Gordon, 1978; Stimson *et al*, 1978; Willis & Osbourne, 1978; Oppenheimer *et al*, 1979; Hartnoll *et al*, 1980; Wille, 1981; Cottrell *et al*, 1985). There was little doubt about the connection between drug-taking and death in many subjects, but in others the link was tenuous.

It is difficult to make meaningful comparisons with the results of previous research, but the outcome in our patients does not appear worse and is in some ways better than that reported from areas where vastly more manpower and financial resources have been poured into the running of treatment centres. It is also difficult to generalise from a study of a population of addicts first seen over a decade ago, but, as little use was made of our treatment facilities, the results suggest that the natural history of those who do not die from their dangerous habits may not be influenced by therapeutic intervention to the extent that we may assume.

Acknowledgements

We are grateful to the patients, their relatives and general practitioners, the staff at Alpha House and other treatment centres, probation and after-care services and the Home Office for providing information; Dr David Machin, Senior Lecturer in Medical Statistics, University of Southampton; the staff of the Southampton Psychiatric Case Register; and Mrs Althea Edwards and Miss Suzanne Kidd.

The Prevalence of Bulimia Nervosa

A Replication Study

PETER J. COOPER, DEBORAH J. CHARNOCK and MELANIE J. TAYLOR

There have been reports of a high prevalence of bulimic episodes and the syndromes of bulimia nervosa and DSM–III bulimia in community samples. A group of American authors recently compared the findings of a contemporary survey with those of a survey they had conducted previously and reported a three-fold increase in the prevalence of DSM–III bulimia. The present study replicates a community survey conducted four years ago in Britain. The prevalence of bulimic episodes, self-induced vomiting and bulimia nervosa found in the present survey was very similar to that found in the earlier study.

Since the specification of diagnostic criteria for bulimia nervosa (Russell, 1979) and bulimia (DSM–III; American Psychiatric Assocation, 1980), there have been numerous epidemiological surveys designed to provide an estimate of the prevalence of these disorders and their constituent components. As yet there has been no rigorous study of a large representative sample using sensitive standardised interview methods of assessment. Virtually all the studies have used simple self-report questionnaire measures on samples of convenience. Many of these studies have produced high prevalence rates. For example, among female American college students, reports of the prevalence of bulimic episodes have consistently been in the region of 60% (Halmi *et al*, 1981; Nagelberg *et al*, 1984; Hart & Ollendick, 1985). Remarkably high rates of the DSM–III syndrome of bulimia have also been reported. For example, a prevalence rate of 8% has been reported among female American high school students (Johnson *et al*, 1984); and among female American college students the rates have been even higher: 14% (Pope *et al*, 1984), 17% (Hart & Ollendick, 1985) and 19% (Halmi *et al*, 1981).

Against the background of these alarming estimates of prevalence, two reports from different continents, both published in 1983, produced significantly lower rates. Cooper & Fairburn (1983), in a questionnaire survey of women attending a family planning clinic in southern England, found that 20.9% reported bulimic episodes, defined as episodes of 'uncontrollable excessive eating'. They used three criteria to define the presence of probable bulimia nervosa: bulimic episodes; self-induced vomiting; and a 'morbid fear of fatness', defined as a response of at least 'often' to the question on the Eating Attitudes Test (Garner & Garfinkel, 1979) concerning being 'terrified about being overweight'. These criteria for 'probable bulimia nervosa' were fulfilled by 1.9%. A similar study was conducted in America (Pyle *et al*, 1983). A questionnaire based on the DSM–III criteria for bulimia was administered to a large group of college students. Among the women, 49.7% reported bulimic episodes, defined as having 'had the experience of rapidly eating a large amount of food at one time in a way that would be embarrassing if others saw you'. The DSM–III criteria for bulimia were fulfilled by 4.5% of the women, but this figure fell to 1% when a stricture was applied of at least weekly bulimic episodes and self-induced vomiting or laxative abuse.

The authors of the 1983 American study have recently reported a replication of their earlier work (Pyle *et al*, 1986). Using their conservative diagnostic criteria, they found the prevalence of DSM–III bulimia to be 3.2% among the female students; and they concluded that this constituted evidence for a three-fold increase in prevalence. The inference that the prevalence of bulimia is rising is questionable, given that the research methods employed in their two studies were very different. However, the difference in prevalence rates obtained by the two American studies suggested that a replication of the British family planning clinic survey would be worthwhile.

Method

The population studied consisted of attenders at two family planning clinics in Cambridge. Over the course of four weeks in January and February 1986, all attenders at these clinics were asked to complete a brief questionnaire. The questionnaire was similar to the one administered in the earlier study and was designed to elicit information on weight and on eating habits and attitudes.

Results

The questionnaire was given to 371 consecutive attenders at the clinics. Thirteen (3.5%) refused to complete it. While waiting to see the doctor, 276 (74.4%) were able to fill in the questionnaire; the remainder were given stamped addressed envelopes and asked to return it by post. Of the 82 women who took their questionnaires away, only 55 (67.1%) returned them.

An initial comparison was made of the demographic features and eating habits of the women who had completed their questionnaires in the clinic and those who had not done so. Since there were no differences between these two groups, the full sample of 331 was examined (i.e. 89% of the original 371 women approached).

TABLE I
Comparison of the 1981–1982 sample with the 1986 sample

	1981–1982 (n=369) %	*1986 (n=331)* %	χ^2	
Age (years)				
15–19	19.8	27.7		
20–24	40.8	36.0		
25–29	22.8	20.1	6.5	NS
30–34	10.1	10.1		
>35	6.5	6.1		
Weight (% MPMW[1])				
≤75	0.0	0.3		
75–85	7.4	11.4		
86–100	52.3	55.7	7.6	NS
101–115	33.7	26.8		
>115	6.6	5.8		
Eating habits				
Current bulimic episodes	20.9	27.1	3.50	NS
Current self-induced vomiting	2.9	2.4	0.09	NS
Current probable bulimia nervosa	1.9	1.8	0.04	NS

1. Matched Population Mean Weight.

Table I shows a comparison of the present sample with the earlier one in terms of age, weight and eating habits. As can be seen, there was no difference between the two groups in terms of age or weight distribution. The mean age of the earlier sample was 24.1, which is no different from that of the present sample (i.e. 23.8; $t=0.67$); and the current mean Matched Population Mean Weight (MPMW) of the earlier sample was 98.0, which is very similar to that of the present sample (i.e. 97.7; $t=0.42$). In terms of the frequency of bulimic episodes and self-induced vomiting, defined identically in the two studies, there was also no difference in prevalence between the two samples. The Eating Attitudes Test was not administered in the present study and a 'morbid fear of fatness' was defined as a response of 'markedly' to the question 'are you afraid of becoming fat?' This represented the most extreme response on a four-point rating scale. Out of the sample of 331, six women reported current bulimic episodes and self-induced vomiting and had a morbid fear of fatness. This represents a point prevalence rate of probable bulimia nervosa of 1.8%, which is almost identical to the estimate obtained in the earlier study.

Discussion

The present study constitutes a replication of an epidemiological survey conducted in Britain in 1981–1982 to determine the prevalence of bulimia nervosa. It was prompted by a report of a three-fold increase in the prevalence of DSM–III bulimia in recent years in America (Pyle *et al*, 1986). In the earlier British study the prevalence of probable bulimia nervosa was estimated to be 1.9%. In the present study, using similar measures on a sample likely to be similar in demographic features, the prevalence rates found for bulimic episodes, self-induced vomiting and bulimia nervosa were very similar to those found in the earlier study. It could be argued that a comparison of syndrome prevalence rates is illegitimate because the two studies used different definitions of a 'morbid fear of fatness'. Since in neither study did a case arise of an individual who reported the disturbed eating habits in the absence of a morbid fear of fatness, and since in both studies the class of those fulfilling the morbid fear of fatness criterion was much larger than the class fulfilling the other two criteria, it is most unlikely both on probabilistic and clinical grounds that the differing definitions had any influence on the syndrome prevalence figures.

It is unclear why the American and British epidemiological research on eating disorders continues to produce such different findings. One reason may be a genuine difference in the prevalence and incidence of disturbed eating behaviour in the two countries. Another possible reason is that different sets of diagnostic criteria are employed and different methods of assessment used. The uncertainty surrounding the epidemiology of eating disorders will remain until common diagnostic criteria are used in studies which employ rigorous and replicable research methods.

Russell (1985) has suggested that the 'cases' of bulimia nervosa identified in questionnaire surveys differ considerably from patients presenting at hospital clinics. Further examination of the 'cases' identified in the present study supports this speculation. Of the six probable cases, all of whom reported at least monthly bulimic episodes, only two reported at least weekly episodes and none reported such episodes occurring daily. In contrast, in a recent series of patients attending a psychiatric out-patient clinic, half had been experiencing bulimic episodes at least daily, and 17% at least twice daily (Fairburn & Cooper, 1984). Thus the prevalence figure of between 1% and 2% for bulimia nervosa obtained in the earlier British survey and confirmed by the present study should be regarded as a prevalence rate of mild disorders of uncertain clinical significance. The rate in the community of cases of bulimia nervosa of the severity seen in psychiatric out-patient clinics remains unknown.

Acknowledgements

We are grateful to Dr S. Stovin and her colleagues in the Cambridge Family Planning Service for their help in conducting this study, and to Dr C. Fairburn for his comments on an earlier draft of the manuscript.

Brief Reports

Validity Study of the Hospital Anxiety and Depression Scale Among a Group of Saudi Patients

The Arabic version of the HAD scale was validated in a sample of 50 Saudi patients. The scale scores were assessed against the principal author's clinical evaluations. Spearman correlations of all items of the scale, except for one, were statistically significant. The non-significance of one item was probably related to the way it was translated into Arabic. The study furnished evidence that the Arabic version was a reliable instrument for detecting states of anxiety and depression in Saudi patients in a primary health care setting.

The Hospital Anxiety and Depression (HAD) scale (Zigmond & Snaith, 1983) was designed to be a reliable instrument for detecting states of anxiety and depression in the setting of hospital medical outpatient clinics. It is brief and limited to the two most common aspects of mood disorder presenting in hospital practice (i.e. anxiety and depression). It is composed of 14 items, 7 for anxiety and 7 for depression. Items representing symptoms of severe mood disorders (e.g. suicidal feelings) or bodily symptoms likely to occur in physical illness have been excluded.

The purpose of this study was to test the validity of the HAD scale in a sample of Saudi patients, as previous studies have only been carried out in the United Kingdom.

Method

No instrument measuring anxiety and depression disorders had been validated in Saudi Arabia before, and therefore it was decided to test the scale against the principal author's clinical judgement, after a formal interview and mental state assessment. The principal author is a British-trained psychiatrist, who has worked in the same geographical area for more than 10 years.

The study was conducted in a primary care health centre situated in the middle of Al-Khobar, Eastern Province, Saudi Arabia. Subjects were consecutive new Saudi patients of both sexes, between the ages of 15 and 65 years, who suffered from a variety of complaints and illnesses. The nature of the study was explained to each patient and it was made clear that there was no obligation to take part. Each patient was then given the Arabic version of the HAD scale to complete while waiting to see the physician. In the case of patients who were illiterates the physician read out the items and helped the patients to complete the scale.

After examination by the physician, every patient was interviewed by the principal author in a separate room, without any knowledge of the scores on the HAD scale. The severity of anxiety and severity of depression were assessed at a comprehensive and standardised interview. Careful enquiry was made about relevant psychosocial background. For anxiety and for depression, patients given ratings of 0 and 1 at this interview were considered to be non-cases, those given a rating of 2 to be doubtful cases, and those given ratings of 3 and 4 to be definite cases.

The HAD subscale scores were compared with the author's ratings for anxiety and depression; rank correlations were also calculated for each item of the HAD scale against the remaining six items in the appropriate subscale. Data from all 50 subjects were used in this analysis. Spearman rank correlation was also used to determine whether anxiety and depression subscales detected different aspects of mood disorder. For this objective, only the data collected from 14 subjects was used; that is, from only those who had a difference of 2 or more points between the anxiety and depression scores in the clinical assessment. The sensitivity and specificity of the HAD subscales were assessed in terms of false positive and false negative rates. The authors of the HAD scale recommend a borderline range for both anxiety and depression subscales; that is, scores of 7 or less as non-cases, 8–10 as borderline cases, and 11 or more as definite cases.

Results

Fifty subjects (25 males and 25 females) were included in the study. Following accumulation of data, statistical tests were done. Correlations between the scores on each of the 14 items and the total of the HAD scores on the other six items in the subscale and the scores of the clinical assessment were calculated.

The item–subscale correlations for all the items in both subscales were highly significant ($P<0.001$), except for one of the anxiety items, the English wording of which is, "I get a sort of frightened feeling like butterflies in the stomach." Similarly, all the items except this one had highly significant correlations ($P<0.001$) with the author's ratings of the respective mood disorder.

The overall total subscale scores correlated significantly with the author's rating: for anxiety, $r+0.88$, $P<0.001$, and for depression, $r=+0.86$, $P<0.001$.

The sensitivity and specificity of the HAD subscales are represented in Table I. This shows that for anxiety there were no false positives or false negatives; in the depression subscale there were no false positives but 2 out of 13 (15%) false negatives.

TABLE I
Distribution of 50 subjects according to total HAD scores and clinical assessment

	Clinical assessment, anxiety subscale			
	Non-cases (0–1)	*Doubtful cases (2)*	*Cases (3–4)*	*Total*
HAD anxiety score:				
0–7	19	8	0	27
8–10	1	4	1	6
11–20	0	3	14	17
Total	20	15	15	50

	Clinical assessment, depression subscale			
	Non-cases (0–1)	*Doubtful cases (2)*	*Cases (3–4)*	*Total*
HAD depression score:				
0–7	20	7	2	29
8–10	0	8	3	11
11–20	0	2	8	10
11–20	20	17	13	50

Data on the 14 patients earlier referred to were analysed to determine whether the HAD subscales differentiated between anxiety and depression. The anxiety subscale correlated significantly with anxiety ($r = +0.83$, $P < 0.001$) but had a negative correlation ($r = -0.41$) with depression. Similarly, the depression subscale correlated significantly with depression ($r = +0.82$, $P < 0.001$) but had a negative correlation ($r = -0.68$) with anxiety. These figures, although on a small subsample, strongly support the view that the HAD subscales are specific to the mood they are designed to measure.

Discussion

The finding that the HAD scale was not specific in pointing out doubtful cases does conform with clinical experience that mild emotional (or neurotic) disorders cannot be judged to be either present or absent with certainty. The crucial and relevant question of 'how much' emotional disorder is existent is resolved by the HAD scale as substantiated by previous results. The borderline range used appears appropriate, since the scale scores and the clinical evaluations proved consistent.

The fact that item 9 of the anxiety subscale, "I get a sort of frightened feeling like butterflies in the stomach", was the only insignificant item is probably due to difficulty in translation of this colloquial English expression. This one item does not affect the overall validity of the scale, but future users of the scale would be justified in substituting a different, although similar, expression referring to a sensation of fear centred in the epigastric region.

The Arabic translation of the words 'anxiety' and 'depression' is not agreed on with certainty among Arabic-speaking psychiatrists, and therefore different Arabic words which are occasionally used to translate them carry no specific and sharp boundaries between them, and some people may use them interchangably. This lack of specificity in Arabic words used to describe those two aspects of emotion give the Arabic version of the HAD scale special valuable weight, particularly when the process of case-finding is being done by somebody not experienced in psychiatry or not mastering the Arabic language. The scale items give clear description of certain emotional situations rather than using words vaguely.

A crucial point is that the essential basis of the depression subscale is anhedonia. Five of its seven items describe this experience in one form or another (Snaith, 1987). The scale, therefore, measures anhedonic depression which is taken to be the best indication of hypomelancholia. Kräupl-Taylor (1966) described the essential hypomelancholic symptoms as a decrease in mental and physical activity, in self-confidence and in enjoyment of pleasure, in addition to lack of energy and initiative in general. It is the view of many workers that anhedonia, if it is persistent and not adequately accounted for by the person's circumstances, is at present the nearest clinical guide to the biogenic depressive disorder. The suggestion needs to be put to the test of critical research (Snaith, 1987). At this stage it can be concluded that there is evidence that the HAD Scale is capable of detecting cases of depressive disorder, in particular mild ones, which are likely to respond to antidepressant drugs.

A Possible Variant of the Neuroleptic Malignant Syndrome

A 20-year-old man developed generalised rigidity and signs of autonomic instability following the introduction of therapy with zuclopenthixol decanoate. A diagnosis of NMS was made, despite the absence of hyperthermia. He recovered on treatment with thiamine, dantrolene, and bromocriptine.

In their recent review of the neuroleptic malignant syndrome (NMS), Abbott & Loizou (1986) emphasised that the cardinal clinical features are the development of hyperthermia, muscle rigidity, and autonomic instability in a patient exposed to neuroleptics. I describe the case of a 20-year-old man who developed generalised rigidity and signs of autonomic instability following the introduction of therapy with zuclopenthixol decanoate. At no time did he develop a pyrexia of over 37°C.

Case report

At an early age the patient was diagnosed as mentally impaired and exhibited problem behaviour. Intermittent aggressive outbursts appeared by the age of 10, and from the age of 13 he showed episodes of bizarre behaviour such as talking to himself and barking like a dog. At this time he was admitted to a mental handicap hospital, but showed increasing levels of disturbance, with scratching, biting, kicking, bizarre talk, and self-mutilation. Diagnoses ranging from schizophreniform psychosis and manic–depressive psychosis to personality disorder were considered, in addition to his undoubted mental impairment. Treatments at various times included promazine, droperidol, sodium valproate, benperidol, sulthiame, lorazepam, carbamazepine, clopenthixol decanoate, and lithium carbonate. None made any appreciable difference. Attacks on staff escalated, and following an attempt to strangle a nurse he was admitted to Moss Side Special Hospital in August 1984 when aged 20.

His self-mutilation and violence towards others continued to cause great concern and a variety of different therapeutic measures, including several different drug regimes, was tried. By May 1986 his medication was carbamazepine (500 mg q.d.s.) (for one year), lithium carbonate (500 mg t.d.s.) (for eight months), procyclidine (5 mg b.d.) and diazepam (20 mg b.d.) (both since admission).

Despite the serum carbamazepine and lithium carbonate levels being within the therapeutic range, his behaviour remained difficult to control and zuclopenthixol decanoate (500 mg weekly) was added. A week later his serum lithium level was found to be 1.96 mmol/l and lithium was withheld. After a further week the level was 0.36 mmol/l and lithium at a lower dose of 500 mg b.d. was re-introduced. On the following day he was noted to be oversedated and ataxic and all drugs were stopped. Two days later he had two brief periods of absence accompanied by localised twitching of his jaw. He subsequently became very disturbed, indulged in head-banging, and the next day showed decreased level of consciousness, uncoordination of his upper limbs and generalised hyperreflexia.

He was transferred to a district general hospital where full blood count, serum multiple analysis, skull X-ray, cerebrospinal-fluid analysis, and computerised tomography scan were all normal. An electroencephalogram showed mild, generalised polyrhythmic abnormalities. No diagnosis was made and he was returned to Moss Side. The next day he was found to be comatose, just responding to painful stimuli, with blepharospasm and generalised extrapyramidal-type rigidity. He showed involuntary facial movements, a blood pressure of 150/90, siallorrhoea and dyspnoea, and was incontinent of urine. On transfer to a neurological unit a diagnosis of NMS was made, despite the absence of hyperthermia (temperature over 37.5°C).

Full blood count was normal, as was a chest X-ray. Serum multiple analysis revealed aspartate transanimase to be slightly raised at 45 i.u./l (normal below 40) and creatinine phosphokinase raised at 289 i.u./l (normal below 100). No traces of lithium or carbamazepine were detected on serum estimation. He required a nasogastric tube and oxygen; therapy with intravenous thiamine, oral dantrolene (25 mg t.d.s.) and oral bromocriptine (5 mg t.d.s.) was initiated. For the next 2–3 days he showed a fluctuating level of consciousness, he was frequently incontinent of urine, and his blood pressure varied from 110/70 to 150/90. The generalised rigidity and involuntary facial movements persisted. Over the next week the rigidity gradually resolved, his conscious level improved and ten days after admission he was ready for discharge.

Discussion

Many aspects of this case fulfil the criteria for diagnosis of the NMS. The patient developed dyskinesia, generalised extrapyramidal-type rigidity, fluctuating levels of consciousness and blood pressure, dyspnoea, siallorrhoea, and urinary incontinence approximately three weeks after the introduction of therapy with zuclopenthixol decanoate. Laboratory tests showed mild elevation of liver transaminases and creatinine phosphokinase, the EEG showed non-specific abnormalities, CSF examination and CT scan were normal. These results are to be expected in the NMS (Abbot & Loizou, 1986), although the levels of creatinine phosphokinase can be much higher than in this patient (Gibb & Lees, 1985), and indeed it might be argued that the raised level found could be accounted for by muscle trauma induced by head-banging rather than skeletal muscle necrosis as in the case of the NMS. Neurotoxicity has been reported when lithium is used with carbamazepine, despite both serum lithium and carbamazepine levels being within their accepted therapeutic ranges (Shukla *et al*, 1984). However, the symptoms reported in these cases were confusion, ataxia, horizontal nystagmus, hyperreflexia, and coarse tremors. None of these, apart from hyperreflexia, were present in this patient.

Despite the presence of so many diagnostic features of the NMS, at no stage was hyperthermia present. Hyperthermia has been considered an essential feature of the NMS, yet in an analysis of 120 case reports, Shalev & Munitz (1986) mention reports of "incomplete forms of NMS, i.e. forms without fever or muscle rigidity". In 1963, Price & Giannini reported a case of a man developing tachypnoea, tachycardia, dyskinesia, and hypertension following the initiation of chlorpromazine therapy and suggested that this represented a subtype of the NMS. I would suggest that this case too represents a variant of the NMS.

The pathogenesis of the NMS is unclear. Excessive dopamine receptor blockade may cause the extrapyramidal symptoms, and hypothalamic blockade may account for the disturbance of autonomic and thermoregulatory function (Szabadi, 1984). There have been suggestions that the extreme muscle spasm in the NMS is sufficient to generate a dramatic rise in body temperature and thus account for the hyperthermia. Evidence for this point of view comes from the effect of dantrolene, a drug acting peripherally on skeletal muscle, which produced a rapid relaxation in muscle tone and simultaneous fall in body temperature in some reported cases (Coons *et al*, 1982; Goulon *et al*, 1983). In this patient at least, the extreme rigidity occurring in the absence of hyperthermia would point to a central origin for the usually noted rise in body temperature.

It is worth noting the development of symptoms despite the previous uneventful use of clopenthixol decanoate. This phenomenon has been previously described, and indeed re-challenge with the original agent may not result in a recurrence of the NMS (Caroff, 1980; Shalev & Munitz, 1986; Abbott & Loizou, 1986). However, this patient had been on lithium therapy, and before the development of the NMS had shown signs of lithium toxicity. It has been suggested that concurrent administration of lithium with a potent neuroleptic may facilitate the development of the NMS due to inhibition by lithium of the compensatory proliferation of dopamine receptors when exposed to a neuroleptic (Szabadi, 1984).

The absence of a typically raised temperature may lead to a delay in diagnosis, as in this patient, and a subsequent delay in treatment. Shalev & Munitz (1986) estimated the mortality rate to be 22%, and Caroff (1980) reported that the risk increases when depot forms of neuroleptic are used. As there is now good evidence that specific treatment with dantrolene and dopamine agonists such as bromocriptine is effective (Shalev & Munitz, 1986), the recognition of *formes frustes* of the NMS is essential. Further research is needed to elucidate the pathogenesis of this puzzling condition.

Acknowledgements

I would like to thank Dr S. A. W. Dissanayake for his permission to report this case.

Self-Inflicted Eye-Injuries

Three cases of self-inflicted eye injuries are described and discussed. A review of the literature shows that several psychiatric diagnoses have been assigned to those who mutilate their eyes, and various unconscious mechanisms proposed to explain this unusual phenomenon.

Self-inflicted eye injuries are uncommon. Despite this they are widely mentioned in ancient literature and assume a prominent place in mythology. The Norse god Odin is said to have given one of his eyes for the right to drink a single draught from the Spring of Mimir, whose waters contained wisdom and understanding. Oedipus, the legendary King of Thebes, gouged out his eyes when he discovered the truth of his ancestry.

The notion of self-blinding for sinful thoughts comes from a variety of sources. St Matthew's gospel contains the exhortation: "And if thy right eye offend thee, pluck it out and cast it from thee; for it is profitable for thee that one of thy members should perish, and not that thy whole body should be cast into hell" (St Matthew ch. 5, v. 29). Self-blinding as a punishment for misdirected thoughts has endowed ophthalmology with three patron saints – Lucia of Syracuse, Triduana, and Medana (Stannard *et al*, 1984).

A comprehensive review of some of the older and less accessible literature showed that self-inflicted eye injuries may occur in a wide variety of situations (Tapper *et al*, 1979). Severe self-inflicted injury, including complete removal of the eye (self-enucleation) is usually associated with psychosis, or organic disorders such as epilepsy, encephalitis, and diabetes. LSD-induced psychosis has been particularly associated with self-injurious behaviour (Rosen & Hoffman, 1972).

Minor injuries may occur in the absence of any demonstrable psychiatric illness, when the motive is usually financial or to escape unpleasant duty. Self-mutilation occurring as a compulsive act is rare, but self-inflicted traumatic cataracts and retinal detachments have been described. A 30-year-old male with obsessive–compulsive neurosis virtually blinded himself by repeatedly hitting his eyes with his hands (Tapper *et al*, 1979).

Self-inflicted orbitocranial injury has been described in attempted suicide. A 44-year-old shopkeeper was admitted to a psychiatric ward following an overdose of barbiturates. Five days after admission he was found collapsed, with right-sided spasticity and a right periorbital haematoma. A diagnosis of cerebrovascular accident was made, but was revised when a straight skull X-ray revealed a ballpoint pen within the cranial cavity. The pen had been thrust through the right orbit, across the midline of the head, into the left tempero-occipital region. It was retrieved by a neurosurgeon, and two years later the patient had a right hemiparesis with some loss of visual fields in both eyes but otherwise normal vision. He described his action as a suicide attempt (Bowen, 1971, cited by Tapper *et al*, 1979).

In a wide-ranging review of the eye in psychiatry, Trevor-Roper (1980) reported a young Frenchman who proffered one of his eyes saying "It just fell out while I was playing cards". A tell-tale drop of blood was discovered on his fingernails. Trevor-Roper describes the eye as a "sounding-board for the travails of the whole persona" and emphasises the rôle of the eye in sexuality. To him the eye is "a sort of sexual surrogate, since it is such a convenient organ of displacement whenever fear, guilt, impotence or despair debar a more physiological outlet". Thus self-enucleation becomes "the final solution".

Case Report 1

A 67-year-old widow attended a casualty department with a history of having "poked" herself in the eye with a pair of scissors. Initially she said that it had been "a silly accident", but later volunteered that she had injured her eye deliberately. She was admitted to the ophthalmology ward where her minor injury was repaired.

Until the time of the incident the patient had been living with her son and daughter-in-law, despite having a house of her own nearby. Her son had tried to persuade her to return to her house, but she felt that she was too old to live on her own. Following her eye injury her son and daughter-in-law refused to allow her to return to their home. They described her behaviour as "manipulative".

The patient was examined by a psychiatric Senior Registrar, who found no evidence of psychiatric illness. In particular there were no depressive features and no cognitive impairment. She would not say why she had injured her eye.

A few days before she was due to be discharged the patient committed suicide by jumping from the fourth floor of the hospital.

Case Report 2

A 21-year-old unmarried NCO was invalided out of the services following the onset of a schizophrenic illness for which he received major tranquillisers. He suffered from auditory and somatic hallucinations and thought-broadcasting. He was convinced that one eye was of immense size and that his pituitary gland travelled out of his eye, damaging other people. In response to these delusions he fired an air pistol at his eye, the resulting damage requiring enucleation.

He continues intermittently to be deluded about his remaining eye, and is at risk of blinding himself during a future relapse.

Case Report 3

A 42-year-old single man with a history of paranoid schizophrenia was admitted to hospital in an agitated state. He had been acting strangely for several days, quoting from the Bible and singing hymns at work. He had absented himself from work for four days, and had returned wearing an eye-patch over his right eye. He refused to discuss the eye-patch, saying "It's a private matter between me and God."

Examination of his mental state revealed paranoid delusions and religiosity. He refused to allow his eye-patch to be removed or his eye to be examined. He made a good response to phenothiazines and later admitted that he had ruptured his eye by pressing with his fingers because "certain forces were tricking me. If thy eye offend thee, pluck it out. It's not as painful as you think."

One year later the remains of his eye were removed surgically. Five years later, during a relapse in his illness, he castrated himself using a razor blade.

Discussion

There have been several attempts over the years to fit self-mutilation of the eye into a single conceptual framework. A moral or religious model is often used by patients themselves, who feel they are carrying out the instructions of the Bible. In the earliest clinical case report the patient quotes from St Matthew's gospel, and a diagnosis of *'délire mystique'* is made (Bergmann, 1846, cited by Rosen & Hoffman, 1972). The case is similar to case report 3 above. The vast majority of Christians interpret the gospel in a symbolic and metaphorical way, but some psychotic individuals demonstrate 'concrete thinking' in their inability to make abstract generalizations.

Some psychoanalysts interpret Oedipus' self-blinding as the equivalent of self-castration, believing in an unconscious equating of the eyes with the genitals. One recent paper stated that "castration fears, failure to resolve Oedipal conflicts, repressed homosexual impulses and self-punishment are ubiquitous in self-enucleation" (MacLean & Robertson, 1976). A review of the literature shows this to be an unwarranted oversimplification (Tapper *et al*, 1979). An alternative psychodynamic paradigm is that the eye represents the symbolic condensation of the self, so that self-enucleation "is a substitute of a part of the body for the whole. It allows one to kill the devilish responsible self and yet live" (Rosen & Hoffman, 1972). This is the concept of "focal suicide". There are similarities between this psychodynamic interpretation and the exhortation in St Matthew's gospel.

Kell Yang *et al* (1981) emphasised neurochemical factors in self-inflicted injury. They noted that self-mutilation has been successfully treated with L-tryptophan and suggested that "biochemical assays of red blood cell purine metabolism should be done in patients with histories of self-inflicted mutilation of the eyes". This approach has received little support, although it may have a limited rôle in Lesch–Nyhan syndrome and Gilles de la Tourette syndrome, both characterised by self-mutilation.

The three cases reported here demonstrate that self-mutilation of the eye is not a single clinical entity. Two patients suffered from severe psychoses, while the third was a lonely woman with no demonstrable psychiatric illness. Ultimately, this form of behaviour may remain incomprehensible and impossible to anticipate. What can be said is that patients who damage their own eyes are likely to be suffering from a high level of distress, and should not be dismissed lightly.

The authors would be interested to hear of similar case reports from other clinicians.

Acknowledgements

We gratefully acknowledge permission to report cases of patients under the care of Dr J. Hughes and Dr J. Dyer.

Paranoid Psychosis as the First Presentation of a Fulminating Lethal Case of AIDS

A 34-year-old heterosexual intravenous drug abuser presented with a paranoid psychosis and was subsequently found to have the Acquired Immune Deficiency Syndrome (AIDS). The patient died 14 days later of generalised septicaemia. The case is reported and the aetiology and pathogenesis of the organic psychosis are discussed. It is anticipated that similar psychiatric manifestations will occur as the AIDS epidemic increases.

The Human Immunodeficiency Virus (HIV) is the retrovirus thought to be the causal agent in Acquired Immune Deficiency Syndrome (AIDS). It infects and destroys T-helper/inducer (T4) lymphocytes, causing profound deficits in cell-mediated immunity. Consequently, the central nervous system is often affected by opportunistic infections and lymphomas (Snider *et al*, 1983). HIV is also neurotropic and may be the direct cause of dementia (Shaw *et al*, 1985; Navia *et al*, 1986), myelopathy (Petito *et al*, 1985) or neuropathy (Ho *et al*, 1985).

HIV was first isolated in France (Barre-Sinoussi *et al*, 1983) and in the USA (Gallo *et al*, 1984) from blood. It was known as Lymphadenopathy Associated Virus (LAV) and Human T-Cell Lymphotropic Virus (HTLV III) respectively.

The number of subjects exposed to HIV is increasing exponentially. The first case of AIDS reported in the United Kingdom was in 1981. By 1 August 1986, 465 cases of AIDS and 234 deaths from AIDS had been reported, and 3162 subjects had antibodies to HTLV III (figures compiled by Public Health Laboratory Service, Communicable Diseases Centre, London). As the epidemic increases, psychiatrists will be consulted more frequently to treat AIDS-related organic brain syndromes, reactions to the diagnosis or its psychosocial consequences.

The following case history is an example of a man who presented with a paranoid psychosis as the first feature of AIDS.

Case report

A 34-year-old married heterosexual plumber was referred to the out-patient department for treatment of heroin-dependency. He first started smoking heroin at the age of 29 years at the time of the break-up of his first marriage. Within two months he was injecting the heroin intravenously, up to 0.5 g/day. Over the next five years (except for a 12-month period of self-enforced abstinence), he continued to abuse heroin. At the same time he started to abuse benzodiazepines, mainly diazepam and chloridazepoxide (40–50 mg/day), which he obtained both from his GP and the black market.

During the eight months prior to his referral to our department he had developed a persistent sore throat and had lost 20 kg in weight. For three weeks he had abstained from heroin following the prescription of a reducing course of methadone. At interview he was an unshaven cachectic man who looked ill. His behaviour was inappropriate, he sucked a bright red lollipop throughout the interview and later pulled out a bottle of methadone and started to drink it.

He was orientated in time, place, and person but was not fully aware of the purpose of our meeting. He talked in a slow monotone and said that he felt anxious and physically ill. He looked perplexed. He believed that his parents' house was infested with bugs and that some of these were inside his stomach eating his methadone. He incorrectly believed that his father was watering down his methadone and selling the remainder. He admitted to seeing fleas on his bedspread a few days earlier and to hearing second-person auditory hallucinations. Cognitive testing revealed slightly reduced attention and concentration. He correctly registered a name and address but could only remember three out of six items at five minutes. His general information was fair.

After this initial consultation he was admitted to hospital. Shortly after admission he became more deluded, believing that he had sunstroke and that one part of his head was lower than the other.

Physical examination: apyrexial, pulse 80/min regular, BP 120/70, oral candidiasis, a cough producing thick green purulent sputum but no localising signs in the chest, and a maculopapular rash on his chest and arms. Investigations: Hb 11.8 g/dl; WBC 4.5×10^9/l with a lymphopenia of 0.23×10^9/l. The film showed anisocytosis, occasional hypochromia and pencil cells; ESR 60/min; total protein 88 g/l; albumen 32 g/l; globulin 56 g/l; liver enzymes normal. Anti Hb Core IgG positive (implies previous infection with hepatitis B); HTLV III antibody positive; sputum grew normal flora only; throat swab grew candida and a staphylococcus aureus.

Chest X-ray: pneumonic consolidation at the base of the right upper and left lower lobe. Electroencephalogram (EEG) showed slightly slow symmetrical alpha rhythm at 8–9 Hz, with even slower medium-voltage theta rhythms at 4–6 Hz in all areas. Computerised tomography (CT) scan showed dilated ventricles, cortical atrophy and enlarged sulci and a marked sinusitis. Lumbar puncture: clear sterile CSF, with normal protein and sugar concentrations.

He was treated with methadone (10 mg t.d.s.), diazepam (10 mg t.d.s.), and chlorpromazine (150 mg q.d.s.). Nystatin suspension and later amphotericin were prescribed for the candidiasis. His delusions resolved over the next five days but he was intermittently mildly confused (worse at night) and disorientated in time. On one occasion he got lost around the ward.

In view of his poor physical state and the good response of his psychosis to neuroleptic medication, it was decided to transfer him to the local infectious diseases hospital for further treatment of his opportunistic infections. He was counselled regarding his HTLV III status and his oral candidiasis, sinusitis, and pneumonia. He denied that there was anything wrong with himself and refused to be transferred. Later that day he absconded and went home. When at home he became more aroused and clearly psychotic. He thought the doctors were imposters and that the hospital was not a National Health Service hospital. He threatened his mother and others with physical harm if he was made to return to the hospital. He was placed on a Section 4 of the Mental Health Act (1983) and was returned to the hospital with the assistance of the police.

It was decided to treat his chest and sinus infection empirically with co-trimoxazole (960 mg b.d.). Twenty-four hours later he became septicaemic following a deterioration of his respiratory infection and was transferred to Intensive Care. A second X-ray showed radiological changes typical of pneumocystis carinii infection. He was ventilated for 72 hours, and died following a prolonged period of intractable hypotension.

Discussion

This 34-year-old heterosexual married man was referred for treatment of heroin dependency and found at interview to have a paranoid psychosis. There was no family or previous personal history of psychiatric illness. An organic aetiology for the psychosis was presumed and was supported by the impairment of consciousness, intermittent confusion, and disorientation (Lishman, 1978). He denied using amphetamines. No-one at this stage had suspected that he might have AIDS. It was only after admission to the psychiatric unit that opportunistic infections, lymphopenia and antibodies to HTLV III were identified meeting Centers for Disease Control criteria for a diagnosis of AIDS (Jaffe *et al*, 1981).

The most parsimonious explanation for the presenting paranoid psychosis is that it was part of the clinical picture of AIDS. There are different ways in which AIDS could have led to the psychiatric syndrome. The central nervous system (CNS) could have been affected directly by HIV infection or an opportunistic infection of the brain, or the psychosis could have been a toxic consequence of opportunistic infections (e.g. pneumonia, sinusitis, fungal stomatitis) outside the brain. Although a toxic state could not be excluded, the findings of clear sterile CSF, diffuse bilateral slowing of the EEG, and the CT scan changes of cerebral atrophy and dilated ventricles would be consistent with HIV infection of the brain (Shaw *et al*, 1985).

The course of the illness was unusually rapid, with death occurring two weeks after presentation, whereas in most reported cases the course of the illness was more protracted. Indeed, the most common psychiatric complication is a dementia developing over weeks or months. It is of interest that the CT scan showed generalised atrophy in our patient, indicating that probably there was a subclinical phase of the damage to the brain prior to the onset of symptoms.

HIV infection of the brain has been variously termed AIDS encephalopathy (Shaw *et al*, 1985; Sharer *et al*, 1986), subacute encephalitis (Snider *et al*, 1983; Nielsen *et al*, 1984) and AIDS dementia complex (Navia *et al*, 1986). It occurs in about one-third of patients with AIDS (Carne & Adler, 1986). The condition is characterised by subtle cognitive changes, confusion, malaise, lethargy, loss of libido, social withdrawal, depressed mood, personality change, and headache, progressing over weeks or months to profound dementia with fits and ataxia. Psychosis has also been described (Hoffman, 1984; Rundell *et al*, 1986). Kleihues *et al* (1985) report a 24-year-old woman who presented with symptoms resembling hebephrenic schizophrenia.

It is now recognised that in AIDS, CNS manifestations are common (Johnson & McArthur, 1986). In a post mortem study, 31 (78%) out of 40 patients with AIDS had significant CNS disease (Nielsen *et al*, 1984). It is important to realise that psychiatric rather than neurological manifestations may be the presenting feature of AIDS (Hoffman, 1984; Kleihues *et al*, 1985) and AIDS dementia can sometimes be the sole manifestation of HIV infection (Navia *et al*, 1986).

There are important practical conclusions to be drawn from this case. In every patient presenting with a psychosis of unknown origin and a history of intravenous drug abuse, AIDS should be suspected and the test for HTLV III antibodies be performed. Such patients can present great difficulties in management: the psychosis may require custodial treatment on a psychiatric ward, whereas the medical complications require urgent treatment on a general medical unit, preferably specialising in infectious diseases.

Koro Syndrome Associated with Alcohol-Induced Systemic Disease in a Zulu

A case report is presented of the genital retraction syndrome, koro, associated with alcoholic hepatitis, avitaminosis and urinary tract infection, occurring in a Zulu male. Treatment of the physical conditions resulted in resolution of the koro symptomatology.

The nosological status of koro is discussed and it is proposed that the condition be regarded as a symptom-complex reaction to a variety of psychological or physical stressors rather than as a purely culture-bound syndrome.

Koro is the popular name given to the genital retraction syndrome originally described by Blonk (1895), characterised by the belief that the penis is shrinking into the abdomen and that its eventual disappearance will lead to death. The subjects are consequently anxious or frightened and have usually instituted some mechanical means to maintain the penis in its external position. Koro has been a periodic focus of interest since the original reports and is no longer regarded as a purely culture-bound syndrome restricted to the Chinese peoples of Southeast Asia as was once the case (Yap, 1965). The cases reported in non-Chinese subjects to date are reviewed by Berrios & Morley (1984), who contend that this group tend to exhibit partial or incomplete syndromes as opposed to the full symptom complex originally described in Chinese patients. Koro has been described as both a circumscribed entity subject to epidemic spread (Sachdev & Shukla, 1982), and as a phenomenon found in other better defined primary psychiatric conditions (Berrios & Morley, 1984). The following case demonstrates an association with systemic physical illness and is the first report of koro occurring in any race group in Southern Africa.

Case report

The patient was a 38-year-old married Zulu male with five children, employed as a casual labourer. He had been resident in Natal, South Africa, his whole life. He presented initially with dysuria, but later elaborated that his penis had been shrinking into his abdomen for the past three days and that he knew he would die when it disappeared completely. This belief was unshakeable despite reassurances to the contrary. He had no previous medical or psychiatric history of note. A brother had been in hospital for a transient psychiatric illness from which he had fully recovered; no further details were available. The patient's wife reported that he drank moderate amounts of alcohol on a daily basis and had done so for many years, with no previous ill effects. Systematic interrogation revealed dysuria with frequency and red-stained urine at times. There were no vegetative features of depression, reports of bizarre behaviour, or recent change in drinking pattern. On examination he was a moderately obese man of pyknic build with a low grade pyrexia (37.6) and symmetrical pellagrinous dermatitis on the face and arms. Central nervous system was grossly intact and all other systems were normal. The urine was dark brown with no macroscopic blood. Mental state examination revealed an awake, alert, fully co-operative man, able to give a logical sequential account. He was notably anxious with congruent affect. The belief concerning the shrinking penis was of delusional intensity: there were no other psychotic features. There were no physical signs of alcohol withdrawal. Laboratory investigations showed a hypochromic macrocytosis and uniformly elevated hepatic enzymes. Venereal disease reference laboratory (VDRL) test was negative; skull and chest X-rays were normal. Urine microscopy showed a low grade haematuria with five leucocytes per high-power field: *Staphylococcus Epidermis* was cultured. He was admitted with the diagnosis of alcohol-induced avitaminosis, alcoholic hepatitis, and urinary tract infection, and commenced on a course of ampicillin, diazepam and vitamin supplementation. The ideas concerning the penis abated after four days without any specific neuroleptic medication, and he gained full insight.

Discussion

This case supports the assertion that koro is not a culture-bound syndrome and suggests that the symptom complex can emerge as a reaction to a variety of non-specific medical or psychiatric stressors. Ang & Weller (1984) consider koro to be a symptom complex occurring in the presence of a hyperacute anxiety state complicating any psychotic illness, whereas Sachdev & Shukla (1982) propose that the term 'koro' be reserved for the acute, short-lasting, circumscribed illness as originally described and that 'koro symptom' should not be included in other psychiatric conditions. This latter view appears unnecessarily restrictive and is not supported by the case reported here or by most of the recent literature. Berrios & Morley (1984) include three cases in their review in which koro symptoms occurred in the presence of systemic physical disease. In his extensive review of the koro literature from an ethnological perspective, Edwards (1984) concludes that the category of genital retraction syndromes is of little nosological significance other than being of heuristic value in drawing together diverse sets of observations. The place of koro within current classification systems (i.e. ICD-9 (World Health Organization, 1978) and DSM-III (American Psychiatric Association, 1980)) remains uncertain. Traditionally regarded as a depersonalisation disorder under the emic transcultural perspective (Yap, 1965), the culture-bound syndrome would by definition be excluded from any nosological category implying psychosis, whereas from the etic transcultural viewpoint the belief that the penis is shrinking would be regarded as a delusion, best subsumed under the categories of Atypical Psychosis (DSM-III 298.90) (i.e. as a monosymptomatic delusion of bodily change) or Psychogenic Paranoid Psychosis (ICD-9 298.4). The presence of organic/physical factors as reported here leads quickly and unequivocally to the diagnosis of Organic Delusional Syndrome (DSM-III 293.81) if the appropriate diagnostic 'decision tree' is followed. Rin (1965) has offered a psychodynamic explanation for the development of the syndrome but this is directly related to the Chinese concept of illness and not to the model of any classical Western psychodynamic theory. Considering the obvious analogies to the Freudian concept of castration anxiety, it is surprising that no recognised authority from any of the established analytical schools has postulated a comprehensive dynamic explanation. Overall it appears that the full or partial koro syndrome manifests in a relatively small number of individuals, suitably predisposed for reasons yet to be determined, from disparate ethnic and cultural backgrounds, at times of psychological and/or physical stress. The nature of the symptomatology is probably a function of the relative importance of sexuality in both the personality of an affected individual and his society as a whole. Total resolution of koro episodes is the rule, but further study of this and related phenomena should provide insights into certain aspects of personality development and organisation that are ubiquitous and appear germane to all cultures.

Ganser Syndrome and Its Management

The literature on the Ganser syndrome is reviewed, and a case history is described. A brief hospital admission is worthwhile for patients with this syndrome, but planning and persuasion are needed.

In 1897, Ganser described two prisoners who developed brief bouts of mental illness characterised by disturbed consciousness, hallucinations, sensory changes of a hysterical kind and characteristic answers to questions. These episodes terminated abruptly, with subsequent amnesia for the episode and complete recovery. He believed the condition to be hysterical and sufferers to be genuinely ill – not malingering. Many English textbooks followed Ganser in regarding the condition as hysterical (Whitlock, 1967).

However, there has been only modest agreement as to which features are necessary for the diagnosis. Mayer-Gross *et al* (Whitlock, 1967) stressed *vorbeireden* (approximate answers, e.g. How many legs has a horse? "3", and apparently foolish answers showing that the question was understood). Fish (Whitlock, 1967) also believed *vorbeireden* and paralogia were diagnostic, and stressed similarities with schizophrenic thought disorder. Whitlock (1967), however, thought that *vorbeireden* alone was insufficient for the diagnosis. He regarded the condition as essentially psychotic rather than hysterical and as one kind of clouded consciousness. Enoch & Trethowan (1979) listed the four essential diagnostic features as approximate answers, clouding of consciousness, somatic conversion, and visual and/or auditory hallucinations (pseudo-hallucinations). There is agreement, nevertheless, that the disorder is not confined to prisoners (Whitlock, 1967).

The aetiology of Ganser is diverse. Schizophrenia is commonly cited, but other causes have been listed, including neurosyphilis, alcoholism and Korsakoff's psychosis, cerebrovascular disease, depression, mental retardation, trauma and artefactual illness.

With regard to the differential diagnosis, Enoch & Trethowan (1979) listed malingering, simulated insanity, true dementia, affective states (pseudodementia), epileptic twilight states, buffoonery state, catatonia and oneirophrenia in schizophrenia. Kiloh (1961) contrasted Ganser with pseudo-dementia, Whitlock (1967) stressing disturbed consciousness in this regard as being characteristic of Ganser. Review of the relevant literature, however, suggests that clouded consciousness may be confined to organic cases (e.g. Whitlock, 1967). Ganser has been clearly distinguished from malingering; in the latter but not in the former the patient is aware of his motivation. Tsoi (1973) concluded from a major investigation that the disorder is best placed on a hysterical–malingering dimension rather than with psychosis. Although there is a consensus for a highly favourable outcome, it is reasonable to suppose that this largely depends on the resolution of the underlying problem or disorder.

The only large-scale epidemiological study appears to be that of Tsoi (1973), who surveyed 1200 admissions to a mental hospital serving the two million people of Singapore. He found 21 suspected and 10 typical cases of Ganser. All were unable to answer simple questions, add up or count (e.g. backwards from 20 to 1), and gave approximate answers (believed by Tsoi to be absolutely characteristic of Ganser). Tsoi concluded that these patients were trying to simulate psychotic illness or exaggerate psychotic experience, according to ideas derived from fellow mental-hospital inmates. The patients came from a wide variety of races and cultures. Most exhibited not all but only some of the features described by Ganser.

As Ganser is not a common disorder (Goldin & Macdonald, 1955) – with probably fewer than 50 cases described – and little is known of its correct management, it is felt that the following case history is interesting and instructive.

Case history

In April 1985, a 26-year-old male patient was remanded to prison for medical reports, having been charged with fraud and deception. Following his arrival there he began behaving in a bizarre way which necessitated his being assessed by one of the authors (MWPC). He claimed that he had served as a mercenary in the Vietnam War, and began demonstrating his skills at kung fu on fellow inmates and staff. He claimed to have alopecia and was seen regularly to pull hair from his head. He was disinhibited, spitting everywhere and smearing the cell with excreta. He was observed apparently replying to non-existent people but declined to explain his strange behaviour. He refused to leave his cell to be interviewed and had to be seen there. He was lying under a dirty blanket and the cell walls were faecally smeared. Once started, he spoke freely and no disorder of talk, behaviour, mood, affect or thought process was discernible. Cognitively he was intact, although there were obvious attempts to falsify his answers, apparently deliberately. Some of his responses were as follows (correct answers given in brackets):

Q. How old are you?
A. 25 [26]
Q. When were you born?
A. In 1962 [1960]
Q. What is the date today?
A. March 1986 [October 1985]
Q. Where do you come from?
A. Vietnam. My parents died when I was five in Vietnam. I married a local girl at 13 and she lives in Vietnam. I was a mercenary during the Vietnam War, serving in the Soviet Army.
Q. How many legs has a horse?
A. 5.
Q. How many legs has a dog?
A. 7.
Q. How many eyes has a cat?
A. Depends on how much he is using its claws.

Later he gave his correct age, and when the inaccuracies in his replies were pointed out, he did not appear concerned. He denied the charges, claimed that he was falsely imprisoned and denied that he was mentally ill. Throughout, there was no unequivocal evidence of hallucinations, delusions, or other psychotic features, and no evidence of treatable psychiatric disorder. No medical recommendation was made, therefore.

He was again assessed in Winchester Prison in April 1986, after he had been refused a place in a regional secure unit, and the Crown Court had ruled that a place be found for him in hospital under Section V(1) of the Criminal Procedure (Insanity Act) 1964. He had been transferred back to Winchester from another prison where he had been since the earlier assessment.

He appeared in a night-shirt and throughout the interview was blank and insouciant. He denied his true name but said he was "Alexander Peron", "on the military warden wing" and that his nationality was "Perronic English". He refused to say where he lived but later denied that he had ever known Harrow, his domicile. To many questions he answered "No" and to others he replied, "That is inconsequential". When asked his age, he replied "18" [26], claimed that he was born in 1960 [correct], but said the year was 1987 and that he was 97 years young. He then changed the year of birth to 1979.

When confronted with his name, he answered, "He is one of my men – an audio-staff sergeant." When asked his regiment, he said "RE, Royal Artillery, Battery A . . .". He refused to say how long he had been in the Army and denied ever serving in the SAS (a claim he had made to the prison authorities). He gave his whereabouts as a "military hospital – the hospital wing". He claimed to know a Gartwick Northerin [? an anagram of Northwick Park]. When asked to spell this he replied "NOPCORXTHEN".

He gave his occupation as "Doctor – a doctor surgical – I don't mean a surgeon – not a pathological – orthopaedics". He then added "Soldiering". When asked where he did this, he replied "Dollon – the inner city" [? anagram of London].

He gave the Queen's name as "Victoria" but did not know her husband's name. When asked for the names of her children, he replied, "I am not one of their army." When asked for the Prime Minister's name he answered, "No consequence – I am not involved in politics." He claimed to be married (untrue) and gave his nationality as "Perronic English". He claimed his wife was guarded by soldiers – "Perronic soldiers". He gave the capital of England as "Dollon", the capital of Scotland as "Aberdeen", of France as "Paris", and of the United States, as "Boston". When asked who was the President of the United States, he said "Farillo" (possibly he meant Ferraro – a name topical in the US at the time). However, he denied knowledge of Gadaffi. His favourite animal was the tiger. When asked how many legs has a horse, a tiger and a cat, he said, "That is a ridiculous question." He claimed to have university degrees and when asked which, he said "Edinburgh University, Pathological, Masonic, Bowie and Akaba", together with "Three fellows' degrees". When asked, "What is Akaba?" he had first replied "A language", then he said, "It is near the Red Sea". When asked, "What is the Red Sea? he said, "It is a lake near Israel".

He claimed to enjoy killing people – "Dead". He then added, "That is a pathological answer, isn't it?" He claimed the prison officers were his staff officers and that he was the platoon sergeant. He had "75 billion" men. When asked whether he heard voices he said, "Yes – somebody on the outside – on the end of a telephone". He then adopted a histrionic listening pose, pointed to his ear and said, "It is an ear lock." He claimed that he had three children and that he had seen them three years ago [untrue]. When asked about his parents, he said they were dead [untrue], and lived in Perronica.

He then added, "Whitehall is in Perronica." He claimed to be able to write Perronican English and obligingly scribbled a lot of nonsense on a piece of paper.

Throughout the interview he remained insolent and indifferent. He talked nonsense as exemplified above, but it was clear that he was in touch with what was happening. Thus he was acquainted with current events, gave several approximate answers when he obviously knew the correct responses, and gave anagrams of several correct replies. He was apparently aware of what he was doing and of talking deliberate rubbish. He otherwise showed no signs of schizophrenia, mania, or other forms of mental illness.

Thus, he appeared to be conveying the layman's idea of madness; that is, the Ganser syndrome. As the prison staff were clear that he had not exhibited any dangerous behaviour, arrangements were made to transfer him to a psychiatric unit.

Subsequently we pieced together the following history of the development of the present condition.

In August 1984 he was psychiatrically assessed at a police station following violence at home when he stuck a skewer into his mother's buttock. He was reassessed in October 1984 and the diagnosis of psychosis was again raised.

However, later that month he dishonestly obtained a British Airways ticket to Dubhai and subsequently made his way to Singapore, where he was admitted to a mental hospital with gross behavioural disturbance. At the request of the managers of the hospital, he was deported. After Christmas in Hong Kong, he reappeared in Bangkok, where he apparently tried to break into the British Embassy at midnight, only narrowly escaping being shot by the Gurkha guard. He was repatriated from Bangkok at a cost of £1519 to H.M. Government.

While awaiting a medical examination at Heathrow he absconded and broke into his parents' house. After three weeks in Aberdeen, he returned to Harrow where he was arrested, set fire to the police cell and was sent to Brixton. It transpired that he had managed to smash up a friend's house, allegedly tried to assault his father with a knife and defaecated outside the house.

His early history is unremarkable. Born in London, he was the fourth of five siblings. He had a normal upbringing in a caring family. His childhood was uneventful and he passed his City and Guilds examination for plumbing and heating with credits at 19 years of age. His premorbid personality was also unremarkable and, apart from a brief experience of amphetamines at the age of 13, apparently he did not abuse drugs or alcohol.

There was no previous history of any significant physical or mental illness and no family history suggestive of mental illness. He first came under psychiatric care in 1980 at the age of 20 when he was briefly admitted under Section 25 of the Mental Health Act. He presented with paranoid psychotic features and a three-month history of gradual change in his behaviour.

Following this he took several small overdoses of drugs. Although he was intermittently under psychiatric care for about five years, with diagnoses varying from a paranoid psychosis to psychopathic personality disorder, an element of deception emerged over the years, and a diagnosis of mental illness was regarded as increasingly unlikely.

Admitted to Northwick Park Hospital in June 1986, he at first continued to behave in a bizarre fashion, talked nonsense and used anagrams. Thus he called himself

"Skroob". After being stabilised on depot fluphenazine decanoate, he suddenly made a marked improvement, became symptom-free and has remained so. A comprehensive physical and neurological investigation was negative.

Discussion

This man presented with a recent history of deception, simulated illness, blatant fabrication and buffoonery. His outlandish claims and statements were transparently untrue. His grotesque behavioural disturbance was on a grand – not to say global – scale. His more bizarre untruths resembled Walter Mitty-isms rather than delusions. He talked and wrote utter nonsense with insouciance. His talk included much rubbish, many approximate and untrue answers, and anagrams of correct replies. His behaviour was sufficiently outlandish as to suggest that it was deliberately 'attention-seeking'. The motivation, however, was obscure. His demonstrations continued in prison but subsided soon after he reached hospital – typical of artefactual illness behaviour (Carney, 1979). He thus conformed to the classical Ganser pattern. However, his quasi-delusions suggested schizophrenia, and this diagnosis was indeed made in 1980, and in support of this is his improvement on being put on depot fluphenazine decanoate. Again, his tendencies to exaggeration and clang associations suggested mania, but the other features of this illness were lacking. Suspicions of drug or alcohol psychoses were not confirmed and there was little in his overall life-pattern to suggest a formulation of aggressive psychopathy. The definitive diagnosis will probably only be made with the passage of time.

How does this case assist in formulating a scheme of management for these uncommon patients? Present advice is conflicting. Hospital admission has been recommended (Enoch & Trethowan, 1979) but found ineffective. Certainly there is a good case for a period of assessment in hospital, because Ganser is possibly merely a presenting symptom of diverse causation and the underlying illness or problem (if any) needs to be identified. This patient's disturbance subsided with admission but, on the face of it, the principle of bringing hospital addicts and illness simulators into hospital seems basically unsound.

However, it may be that our patient has schizophrenia after all, and a satisfactory outcome, however inadvertently, may be achieved with treatment of that condition. This patient certainly improved following admission, but whether this was due to admission to hospital as suggested by Enoch & Trethowan (1979) or to the initiation of antipsychotic medication is unclear. Because of conduct disorder, these patients are likely to appear to forensic psychiatrists.

The hospital staff were reluctant to have this man in and these people are likely to be unpopular patients. However, a brief admission would be worthwhile if it clarified the diagnosis and apparently produced remission, as in our case. Much planning and persuasion of hospital staff have to be undertaken if admission of such patients is contemplated.

MAOIs and Narcotic Analgesics

SIR: Brown & Linter's review (*Journal*, August 1987, **151**, 210–212) was a welcome review of the confused area of interactions between MAOIs and narcotic analgesics, and provided some useful practical guidelines.

The interaction between dextromethorphan and the MAOIs is, however, contentious. The authors refer to a letter by Rivers & Horner (1970) concerning a patient receiving phenelzine (60 mg/day) who died after consuming 2 oz (about 55 ml if standard fluid ounces are assumed) of a cough mixture containing dextromethorphan. This is open to question, as the dose of dextromethorphan was not stated, nor the other ingredients of the preparation, and nor could the death of the patient definitely be attributed to an interaction (Ascione, 1976). A second letter in the same journal also reporting a dextromethorphan–MAOI interaction death (Shamsie & Barriga, 1971) is similarly doubtful, as the preparation also contained phenylephrine, a drug known to interact adversely with MAOIs. Animal experiments (Sinclair, 1973) show an interaction between dextromethorphan and MAOIs. However, the fatal doses used in the rabbits were very high, and a similar reaction can also be produced with imipramine in rabbits. The strict relevance of these animal studies must thus be questioned, since imipramine and MAOIs are used in clinical practice together, albeit with great care, without reported incidents.

The statement that dextromethorphan is absolutely contra-indicated with MAOIs must thus remain open to considerable doubt.

Comparison of Electrical Measurements on Constant Voltage and Constant Current ECT Machines

SIR: When calculating the energy produced by the constant voltage ECT machine (*Journal*, August 1987, **151**, 244–247), we used a formula based on the assumption of a 50% modified sine wave. The manufacturers (Ectron) state that the machine produces "55% sine waveforms". Examination of the curves produced by the machine in our trial indicates that the waveform is more accurately described as a 60% modified sine wave. In the latter case we have underestimated the energy produced by the constant voltage machine by approximately 40%. Consequently, all quoted values for energy produced by the constant voltage machine should be multiplied by 1.39. The conclusions in the paper are unaffected by the above.

I am grateful to Dr Barrington of Herrison Hospital, Dorchester, for pointing out this error.

Self-poisoning

Sir: I take the point raised by Halasz (*Journal*, August 1987, **151**, 267) when he mentions my use of the word 'epidemic' in describing a rise in incidence of deliberate self-poisoning in the 1960s and early 1970s (*Journal*, May 1987, **150**, 609–614). I would, however, like to reduce any confusion that might arise from his letter by reminding readers that I was referring not to a suicide epidemic, but to a rise in the incidence of deliberate self-poisoning, the vast majority of instances of which are parasuicides, i.e. non-fatal acts.

Late Paraphrenia

Sir: Grahame's letter about late paraphrenia (*Journal*, August 1987, **151**, 268) raises important issues which are dealt with rather too casually. Holden may, no doubt, wish to answer criticisms directed at his paper, but it is worth pointing out that he could not possibly have interviewed his patients using the Geriatric Mental State (GMS) since attentive reading of his text will show that the study was a retrospective one based on case notes.

Grahame appears unshakeable in his belief that late paraphrenia is merely a form of schizophrenia in old age because of the high proportion of cases with first rank symptoms in his sample. We would suggest that both the history of the concept and the results of more recent, systematic prospective studies using the Geriatric Mental State (Naguib & Levy, 1987) should lead to a more cautious approach to this perennial problem. As we have pointed out elsewhere (Levy & Naguib, 1985), the proportion of patients with first rank symptoms in our own larger and unselected group of patients studied prospectively was much lower (16 out of 43, compared with Grahame's 14 out of 25). Thus, even if one accepts the debatable proposition that first rank symptoms necessarily indicate schizophrenia, clinical evidence does not indicate a simple equivalence between late paraphrenia and schizophrenia of late onset. Furthermore, the evidence from HLA sub-typing points in the opposite direction (Naguib *et al*, 1987).

The role of organic factors, both as reflected by cognitive tests and by CT scan measures (Naguib & Levy, 1987), is also rather more complex than Grahame is prepared to concede. We have found minor cognitive changes and ventricular enlargement in a group of late paraphrenics, and follow-up 3.7 years later did not suggest that this was a harbinger of 'organic brain syndrome', as Grahame seems to believe, nor did it bear any obvious relationship to the clinical picture in the survivors (Hymas *et al*, in preparation).

The concept of late paraphrenia or persistant persecutory state in the elderly is one which is peculiarly robust. It is unfortunate that the draft of ICD–10 (World Health Organization, 1987), currently undergoing field trials, will, if accepted, mean that such patients will be distributed among at least four different sub-categories, thus making them somewhat difficult to identify. Nevertheless, identification should be possible, and we believe that the application of a variety of new techniques to the investigation of the problem should begin to clarify the nosological status of this entity or entities. In the meantime, it would be wise to keep an open mind about the question rather than to adopt unduly dogmatic attitudes towards it.

Comparative Trial of a New Antidepressant

Sir: I strongly agree with Dunn's comments (*Journal*, August 1987, **151**, 269) on the study by Levine *et al* (Journal, May 1987, **150**, 653–655), comparing fluoxetine and imipramine.

There can surely be no doubt that new putative antidepressant compounds require testing against placebo in properly controlled double-blind studies before their efficacy can be regarded as established. Comparative trials against other 'established' antidepressants can never prove the efficacy of a new compound (although studies against the standard may have a place later in a compound's development). The main problem with trials against a standard antidepressant is that the investigators predict no difference between the two groups of patients. However, there is no way of testing the absence of a difference between groups. In contrast, testing a compound against a placebo leads to the prediction of a difference which can be tested by ordinary statistical techniques. Indeed, it is extremely easy to obtain a result of no difference between two treatment groups. One simply enters too few patients for statistical significance or makes any of the other design errors which beset even the best psychopharmacology trialists.

To take an example from the Levine *et al* study, patients in the imipramine comparison group were treated with 75–150 mg/day. In the event seven patients were treated at the 75 mg dose. This is well accepted to be inadequate, and a recent study (Thompson & Thompson, in preparation) confirms the inefficacy of 75 mg of a tricyclic antidepressant. Thus, one-third of the standard treatment group received a treatment which was no better than placebo, and a fluoxetine-treated group faired no better in terms of outcome than the imipramine-treated group. I would suggest that this study does not provide evidence of the effectiveness of fluoxetine as an antidepressant, and that only studies against placebo can do this.

There is one point on which I would disagree with Dunn. The use of atropine as a comparison treatment in antidepressant studies is in doubt, as it induces not only the side-effects of the older antidepressants but also may have some intrinsic antidepressant activity. The more appropriate "active placebo" would be methscopolamine, which has peripheral anticholinergic effects but does not pass the blood–brain barrier. Unfortunately, this compound is difficult to obtain and is thus not frequently used. However, in view of the relative lack of anticholinergic effects in the newer generation of antidepressants which are currently being tested, this may not be such a major flaw in current antidepressant trial design.

If psychopharmacologists are shying away from placebo-controlled antidepressant studies for ethical reasons, or if ethical committees are refusing to pass placebo-controlled studies, then they should consider the ethical implications of allowing a potentially ineffective antidepressant or any other compound onto an already overcrowded market.

The Symbolic Significance of Munchausen's Syndrome

SIR: Cremona-Barbaro's paper on the symbolic significance of Munchausen's syndrome (*Journal*, July 1987, **151**, 76–79) prompts comment. Fanciful, dramatic and grandiose presentation is the hallmark of the Munchausen patient, and there may be some relationship between feigned bereavement and the syndrome, but it is by no means "the most common story" (Scoggin, 1983). There has been no previous mention of preoccupation with opera and operatic themes in the literature. Certainly none of our patients exhibited any such interest in the arts (O'Shea, 1987: personal communication).

The aetiology of Munchausen's syndrome would seem to be multifactorial, but there is growing evidence to support a transgenerational learning theory of maladaptive communication patterns with roots in early childhood (O'Shea, 1982; Meadow, 1982).

SIR: It is difficult to know exactly what is "the most common story" given by Munchausen patients presenting with psychosocial symptomatology. Feigned bereavement is commonly accepted to be a very frequent presentation (Simpson, 1978; Snowdon *et al*, 1978), and will be familiar to psychiatrists and to those working in A & E departments. It is overwhelmingly the commonest story given in my own small series of Munchausen patients presenting with psychiatric symptoms.

I would agree that there has been no previous mention of a preoccupation with the opera in the world literature on the Munchausen syndrome. Had there been, my point may have been less worth making. In my own experience, these patients refer to the opera more often than one would expect. A case report published some years ago illustrates this point (Cremona-Barbaro, 1983).

I would certainly not disagree with the view that the aetiology of the Munchausen syndrome is likely to be multifactorial, and it would seem reasonable to assume that maladaptive learning in early childhood is an important factor.

Down-regulation of Post-synaptic Serotonin Receptors as a Mechanism for Clomipramine-induced Anorgasmia

Sir: In considering likely mechanisms for clomipramine-induced anorgasmia, Monteiro *et al* (*Journal*, July 1987, **151**, 102–106) have discounted an effect on central serotonergic transmission. When, however, an injection of a post-synaptic serotonin receptor agonist, 5-methoxy-N, N-dimethyltryptamine (5-MeODMT), is used to induce ejaculation in rats, this effect can be blocked by selective serotonin uptake inhibitors (Renyi, 1986). A single dose of zimeldine inhibits ejaculation when given 48 hours before administering 5-MeODMT. In contrast to Renyi's findings at 48 hours, Mas *et al* (1985) found that zimeldine, like 5-MeODMT, facilitated ejaculatory reflexes when animals were tested one hour after dosing. They also demonstrated that zimeldine's effect on ejaculation, unlike that of the direct agonist, does not occur in animals bearing mid-thoracic spinal cord transections, demonstrating that 5-MeODMT exerts its agonist effect directly on serotonin receptors in the spinal cord or periphery, while zimeldine's effect depends on intact supraspinal innervation.

Taken together, these drug-induced changes in ejaculation can be interpreted as a reflection of the sequence of synaptic events that follow serotonin re-uptake blockade, namely an initial increased concentration of intrasynaptic serotonin with enhancement of neurotransmission, leading to down-regulation of post-synaptic serotonin receptors establishing functional inhibition of neurotransmission by 48 hours (such down-regulation of serotonin receptors has been demonstrated within 3 hours of drug administration by Koshikawa *et al* (cited by Renyi, 1986).

As Mas *et al* point out, the lumbosacral segments of the spinal cord receive descending serotonergic fibres from the raphe nuclei in the same laminae of the anterior horn as the motor and autonomic preganglionic neurones innervating the genitalia.

Chemically-induced ejaculation in paraplegic rats may seem a questionable anthropomorphism to serve as a model of the human orgasm, but this research is cited merely to suggest that serotonergic dysfunction is the best hypothesis for clomipramine-induced anorgasmia.

There have been two case reports of antidepressant-induced anorgasmia in which normal orgasmic function was restored by treatment with the serotonin receptor agonist cyproheptadine while antidepressant treatment was continued (Decastro, 1985; Sovner, 1984). While neither of these cases implicated clomipramine, both drugs – a MAOI and nortryptiline – are known to exert a similar influence on serotonergic transmission. It remains, therefore, to test the acceptability and efficacy of cyproheptadine as a treatment for antidepressant-induced anorgasmia.

Abnormal Intestinal Permeability: An Aetiological Factor in Chronic Psychiatric Disorders?

Sir: Wood *et al*'s paper (*Journal*, June 1987, **151**, 853–856) presents some puzzling areas which are in need of clarification. The authors stated that the mean cellobiose recovery rate after intravenous injection was 28% (s.d. = 10.8%) in patients who showed an abnormal ratio after oral testing and 29.3% (s.d. = 17.7%) in those with a normal ratio, over a five-hour period, concluding that there was no significant difference between these two groups of patients in the metabolism or excretion of this probe molecule after absorption. These recovery rates after intravenous injection are extremely low; indeed, in their previous work (Cobden *et al*, 1985) a mean cellobiose recovery rate of 52.0% (s.d. = 14.3%) was reported, and Menzies (unpublished) obtained an 83.4% recovery rate in normal subjects over the same time period. Irrespective of whether the patients had a normal or abnormal cellobiose/mannitol recovery ratio, due to the low cellobiose recovery intravenously in both populations one might conclude that considerable systemic metabolism of this probe marker had occurred. However, cellobiose, in common with most other disaccharides, is not known to be significantly metabolised within the body (Menzies, 1974). As intravenous cellobiose was not administered to a population free of psychiatric illness, these results would equally well support the hypothesis that patients with chronic psychiatric illness demonstrate abnormal systemic metabolism of cellobiose.

The authors acknowledged the low recovery rates of both probe molecules, postulating that this may have been due to inaccurately timed urine collections, leading to a similar reduction in recovery of both molecules, leaving the cellobiose/mannitol ratio unaffected. However, the mean mannitol recovery rate of 49.45% (mean, abnormal/normal patients) is almost identical to the 49.9% recovery in normal controls (Cobden *et al*, 1985), but the cellobiose recovery ratio is some 23.35% lower (52.0%, compared with 28.65%). This disproportionate lowering of the cellobiose recovery rate is not compatible with error introduced by inaccurately timed urine collections.

Furthermore, it is unclear whether the test solution administered was hyperosmolar. If it was, it is important that subjects refrain from drinking water for at least two and a half hours before and after the commencement of the study, as water would act to dilute the hyperosmolar stress, leading to difficulties in interpreting the results. As the authors have alluded to difficulties in obtaining complete timed urine collections in this group of patients, it would be reassuring to know that 'fasting' included preventing the subjects swallowing water throughout this period, a somewhat natural reaction after ingesting an extremely sweet sugary drink.

Menzies, I. S. (1974) Absorption of intact oligosaccharide in health and disease. *Biochemical Society Transactions*, **2**, 1042–1047.

Sir: We are grateful to McGauley for drawing attention to the low five-hour recovery of cellobiose after i.v. injection in patients with chronic psychiatric disorder. As stated, the recovery is some 23% lower than in the previous study in fit, co-operative volunteers. In theory this could be due to altered metabolism, but may reflect difficulty ensuring complete bladder emptying before starting and at completion of the test in the patients we studied. It is incorrect to presume that the abnormality demonstrated in the oral test could have been due to metabolic differences, as this would have given rise to an apparent reduction in permeability to cellobiose, whereas in fact we have demonstrated the opposite.

The purpose of the i.v. test was to compare the group of psychiatric patients with abnormal oral tests with those who had a normal oral sugar test. The i.v. injection was given before the patient was allowed away from his bed and after a urine specimen was collected. The patients did not have access to food or water during the five-hour period when all urine passed was collected. Endoscopy was performed at the end of the i.v. test and no excessive gastric contents were noted. The i.v. test therefore confirmed no significant difference in metabolism or excretion in the two groups studied.

The composition of the oral test solution is clearly stated in the method section. Patients were asked not to drink, but in order to retain co-operation some freedom was allowed and it is possible that some may have drunk water during the study. However, this would tend to reduce permeability to cellobiose, whereas in fact the study demonstrated an increased permeability to cellobiose in the abnormal group.

Mental handicap and double-blind trial design

Sir: The title "Lithium in the treatment of aggression in mentally handicapped patients: a double-blind trial" (*Journal*, May 1987, **150**, 685–689) raises an interesting question about how the limited conceptual ability implicit in mental handicap might interact with the conceptual sophistication necessary to understand a double-blind design. That the interaction between mental handicap and a double-blind design might have undertones is conceded in the statement, "The nature of the trial and the procedures involved were explained to each patient (at an appropriate level) and to a relative or responsible guardian". Just how much each participant actually understood is unknown, however, because of the lack of operational criteria showing that they understood, as distinct from being in receipt of an explanation. It appears that an opportunity to establish such criteria was lost; for example, each participant should be able to explain the procedure back to the researcher.

However, the more compelling scientific issues concern the other half of the "double-blind" design, the researchers. The outcome variable, levels of aggression, was assessed daily by the nursing staff on duty, who differed during the study; none of them were asked to guess the allocation of the patients. This would have been a prudent precaution given that, "The initial daily dose of 800 mg lithium carbonate was not sufficient, in most cases, to bring the serum lithium concentrate above 0.7 mmol/litre, and subsequently dosage adjustments were needed...". But we are not told that equivalent adjustments were made for the patients receiving placebo, so that one wonders what the nursing staff made of a group of patients who were having their medication adjusted and another group who were not having such adjustments.

Also, side-effects may have betrayed treatment allocation. Although the medical officer assessed each patient for the occurrence of possible side-effects of lithium treatment both before the trial and after one, two, three, six, nine, and twelve weeks, it is naive and unnecessary to suppose that these results, arising as they do out of interviews at specific points of time, generalised to what may have passed between the patients and the nurses who look after them 24 hours a day. It would have been easy to test the nurses themselves. Again, what was the mnesic ability of these patients? How reasonable was it to suppose that at an interview at a given point in time they would recall what had happened in between those points in time?

With this perspective, the authors' claim that blindness was maintained because classical side-effects were noted in 36% of the lithium patients and 20% of placebo patients is unwarranted, particularly as the exact means whereby the side-effects were detected remain apocryphal. Did the medical officer await spontaneous complaints? Did he or she ask a direct question, and if so what question? Was a check-list used?

Why were the measures of aggression made by different members of nursing staff? Given that they were, why was there not a reliability study of these staff? Given that there wasn't such a study, why were the results not analysed for individual nurses? The five-point scale whereby level of aggression was assessed is, on paper, no better than ordinal, the more so given that it may have been used in different ways by the different nursing staff; there was therefore good reason to suppose that the scale did not have interval qualities, and no evidence was presented to gainsay that, so how do the authors justify the use of parametric statistics?

RUTH DARK
EDWARD ROGERS

Greaves Hall Hospital
Banks, Merseyside PR9 8BL

SIR: According to the Declaration of Helsinki, "In any research on human beings each potential subject must be adequately informed of the aims, methods, anticipated benefits and potential hazards of the study and the discomfort it may entail.... Where physical or mental incapacity makes it impossible to obtain informed consent... permission from a responsible relative replaces that of the subject in accordance with national legislation". Thus it is not necessary for a mentally handicapped patient to be able to understand a double-blind design in order to participate in such a trial.

Regarding blindness, in the method section of our paper we described how dummy results for serum lithium concentrations were provided for placebo patients. The medical officer responsible for each patient adjusted the dosage of trial medication accordingly, so that both he and the nursing staff remained unaware of whether the patient was being treated with lithium or placebo.

Records were kept by the nursing staff of the type, duration, and severity of side-effects, as and when they occurred, using a check-list of common lithium side-effects.

It cannot be possible in a hospital to have daily assessments carried out by the same person over a 16-week period. Before undertaking this trial we carried out a reliability study, using the same 5-point rating scale for aggression, to assess the correlation between scores given by different nurse assessors. Statistical analysis of the results showed that while the score of 2 (mood uncertain) was the least reliable, scores of 1 (well-behaved) and 3 or more (overt aggression) achieved satisfactory levels of correlation between separate assessors. For this reason the analysis of our trial results concentrated on these scores.

In our trial it seemed reasonable to use parametric methods for analysis of the scores obtained with the

5-point scale because the data being analysed were themselves summary statistics. However, due to the discrete nature of the data, and to the question of how different intervals on the fixed point scales related to each other, it would, alternatively, have been appropriate to adopt a non-parametric approach.

Gilles de la Tourette's Syndrome in Down's Syndrome

SIR: We recently documented the occurrence and treatment of Gilles de la Tourette's syndrome (GTS) in an individual with Down's syndrome (*Journal,* May 1986, **148**, 601–604). Corbett (*Journal,* April 1987, **150,** 569) suggests that carbamazepine may have accounted for the late onset of GTS in this patient. However, as we indicated in the case report, the patient had been observed by nursing staff to have consistently displayed motor and phonic tics since the age of 11, when she was first institutionalised. We also mentioned that GTS had been diagnosed according to DSM–III criteria, which stipulate that age of onset must occur between 2 and 15 years. In contrast, carbamazepine had only first been used by this patient when she was aged 24, following the onset of a possible seizure disorder.

Corbett correctly points out that pharmacological compounds are increasingly being recognised as precipitants of tics. As indicated in the case report, although we attempted to correlate the presence and frequency of tics to the patient's previous use of medication we felt unable to do so accurately in view of the limited information available. However, tics appeared to have been continuously present since at least the age of 11, an interval that spanned the non-continuous use of several medications specified in the case report, and antedated the introduction of carbamazepine by 13 years. Although carbamazepine possibly exacerbated her symptomatology, it was clearly not responsible for the onset of GTS manifestations in this patient.

Onset of Schizophrenia in Men and Women

SIR: Stromgren has referred to studies indicating that onset of schizophrenia occurs later in women (*Journal,* January 1987, **150,** 1–7). Our experience in India is different.

We have been engaged in a multicentre 5-year follow-up study of schizophrenia, sponsored by the Indian Council of Medical Research, to find out factors associated with the course and outcome of schizophrenia. The centres selected for this study were Lucknow, Madras, and Vellore. All patients who attended psychiatry clinics in the participating centres between 15 October 1981 and 15 October 1982 and who satisfied a modified form of Feighner's criteria for the diagnosis of schizophrenia were included in the study (245 men and 141 women) (Verghese *et al,* 1985). The age of onset was calculated from the age of the patient at the time of inclusion and the time when the earliest abnormality was noticed (duration of illness). Both these pieces of information were given by the close relatives of the patients. Age of onset was found to be 25.87 ± 6.67 years for men and 25.89 ± 7.33 years for women, which suggests that age of onset of schizophrenia is not later in women in all parts of the world.

Chronic Schizophrenia and Long-Term Hospitalisation

Sir: It is always useful for a psychiatrist interested in long-term patients to re-read *Institutionalism and Schizophrenia* (Wing & Brown, 1970), as Wing has reminded me (*Journal*, January 1987, **150**, 129–130). I had hitherto thought that to do so with an eye to the questions it raises was fully in tune with the authors' intentions.

I do not dispute the book's conclusion that the negative handicaps of patients with schizophrenia are influenced by their current social milieu. My letter (*Journal*, September 1986, **149**, 382) was prompted partly by concern that its evidence was given insufficient weight by Mathai & Gobinath (*Journal*, May 1986, **148**, 509–516). I raised the different question of whether or not the institutional environment has a *cumulative* effect on negative handicaps such that they worsen progressively in the long-term, contrary to the case outside hospital (Bleuler, 1978).

I find it difficult to accept Wing's assertion that no one pattern of relationship between negative handicaps and length of stay in hospital is described. A summary (p. 87) states that "patients who were living in the most under-stimulating social environment were likely to show the greatest clinical poverty, and this complex was likely to be more severe the longer the patient has been in hospital"; a graph is said to show (Fig. 4.4 and p. 82) "the striking relationship between length of stay and three other factors, one 'primary' (social withdrawal), one 'secondary' (attitudes to discharge), and one 'social' (contact with the outside)"; and most revealingly (p. 183), "if social improvements had not been taking place at the hospitals the tendency would have been for the patients to have become more withdrawn and reticent, simply with the passing of the years. That such deterioration was mainly prevented, and that so large a proportion as one-fifth of the patients actually improved, is a considerable achievement".

I pointed out that the longitudinal course of individual patients shows the same tendency for deterioration to be concentrated in the early years, with later consistency, or even improvement, described outside hospital. The statistical association between length of stay and negative handicaps appears to result from selection combined with changes in the initial pattern of schizophrenic symptoms (Abrahamson, 1983).

The methodological issue is illustrated by Wing & Brown's treatment of the association between length of stay and unfavourable attitudes to discharge. The same graph is used to calculate the rate at which patients supposedly changed their attitudes year by year and leads on to the recently reiterated conclusion (Wing & Furlong, 1986) that negative attitudes accumulate gradually as part of a process of 'institutionalism'. This assumes that patients' initial attitudes have always been similar and ignores the possibility that those changes that do accumulate may follow discrete events such as loss of family or a home or transfer to a particular ward.

As the institutional era winds down it is important to refine the information with which we are left. That negative schizophrenic symptoms may be sensitive to the immediate effects of an impoverished environment yet resistant to its assumed long-term, cumulative moulding is relevant to future care and to any socio-medical model.

Equally, evidence that attitudes to discharge reflect realities rather than being explained by the gradual development of a secondary handicap has practical and ethical implications (Abrahamson & Brenner, 1982).

DST in Apathetic Hyperthyroidism

Lahey (1931) drew attention to a form of hyperthyroidism which he called 'apathetic hyperthyroidism', occurring mainly in the elderly and lacking many of the cardinal features of thyroid overactivity. The predominant features were depression and apathy, and subsequent reports have confirmed his initial description (Thomas *et al*, 1970; Brenner, 1978). We report a patient fitting the description of apathetic hyperthyroidism in whom the dexamethasone suppression test (DST) was carried out.

Case report: A 69-year old widow presented with a three and a half year history of social withdrawal and isolation to the degree that in the six months prior to presentation she led the life of a recluse. In addition, she complained of persistent depression, hopelessness, loss of interest, loss of drive, anergia, and suicidal ideas. On examination she appeared thin and frail. Her pulse was 76 per minute and regular, blood pressure was 130/80 mm Hg. There were no tremors, eye signs, or goitre. A diagnosis of depressive illness was made and she was prescribed lofepramine. In addition to other routine investigations thyroid function tests were made, and the results showed a raised serum thyroxine (167 nmol/l, reference range 50–150 nmol/l) and a low TSH (0.1 mU/l, reference range 0.5–5.0 mU/l). DST showed normal suppression of cortisol levels. A diagnosis of apathetic hyperthyroidism was made and she was started on carbimazole (10 mg tds).

Apathetic thyrotoxicosis occurs most often in elderly patients, and the salient characteristics that are helpful in establishing the diagnosis include typical placid apathetic facies, a small goitre, the presence of depression or lethargy, absence of ocular manifestations usually associated with hyperthyroidism, substantial muscular weakness and wasting, excessive weight loss, and cardiovascular dysfunction with atrial fibrillation (Thomas *et al*, 1970). Our patient showed many of these features. It is also of interest that the DST showed non-suppression. This is a confirmation of the reports by Kronfol *et al* (1982) and Martin & Waltz (1984), showing that DST is unaffected in depressions secondary to thyrotoxicosis.

The pathogenetic events leading to a state of apathy and depression in these patients is unknown. However, it has been postulated that there is a depletion of catecholamines or a lack of end-organ sensitivity following continual stimulation of the sympathetic nervous system.

A diagnosis of 'apathetic thyrotoxicosis' must be borne in mind when an elderly patient presents with symptoms of depression and apathy. Treatment of the endocrine dysfunction will often produce a marked improvement of the condition.

We acknowledge the assistance of Dr Oyebode.

Catatonic Signs in Schizophrenia

SIR: Catatonia is a not uncommon syndrome of varied aetiology (Gelenberg, 1976). We report a patient with catatonia in whom a curious combination of catatonic signs existed. Our use of terms is in accordance with the definitions of catatonic signs cited by Hamilton (1976).

Case report: Mrs L, a 60-year-old institutionalised patient with chronic schizophrenia, was prone to episodes of transient catatonic stupor, usually lasting a few hours at a time, at a frequency of about one per year. Despite extensive biochemical, radiological and electroencephalographical investigation no causative factor was demonstrated, and the catatonia was concluded to be a stress-related feature of her schizophrenic illness. The catatonia was invariably characterised by stupor and diffuse waxy flexibility.

During one episode of stupor, however, we noticed that different parts of her body responded differently to the examiner's touch. Active negativism was present from the neck up: there was strong resistance to the examiner's efforts to open her eyelids, lower her jaw or rotate her head. Waxy flexibility characterised her upper limbs: these could be moulded into positions which were maintained for several minutes despite potential discomfort. *Mitgehen* was demonstrated in her lower limbs: gentle pressure led to the limb moving readily in the direction of the applied pressure, despite the examiner's injunctions that she need not move. It thus appeared that there existed a cranio-caudal gradient of voluntariness to movement in obedience to the examiner's guidance, leading to what would seem to be a combination of logically antithetical catatonic signs. She recovered within three hours; her subsequent course was uneventful.

We are unable to ascribe any clinical significance to this combination of seemingly antithetical catatonic signs.

Chronic Depression in General Practice

SIR: After 10 years in general practice I have developed a small following of people suffering from chronic depression. Turning to the textbooks for help with management, I discovered that of 14 by British authors, 10 of which were published since 1980, only one had a reference to the problem in the index and this was the only book to have a section (of some substance) devoted to chronic depression. Resistant depression was mentioned in two other books, but I detected uncertainty as to the definition of this. I realise the distinction between the two may be difficult, sometimes only to be made after a long time. However, they are different, and possibly some clarification is needed here.

Other reading suggests that it is a significant problem which has been recognised for several years: a leading article in the *British Medical Journal* (1971), after examining a variety of studies, suggested that "for practical purposes we would not go far astray if we reckoned that one-fifth of our severely depressed patients would become chronic." DSM–III suggests that in 20–35% of cases of major affective disorder there is a chronic course. However, it is not clear how they would classify it, dysthymic disorder being otherwise entitled depressive neurosis. At an international symposium Kieholz (1972) discussed chronic depression – "an important, albeit somewhat neglected, form of the disease".

The management of acute endogenous depression, once identified, seems relatively easy with careful assessment, optimistic support, social consideration, medication, and sometimes hospitalisation and ECT. The management of chronic endogenous depression seems more difficult, all of these aspects of care presenting greater problems. I would be interested in readers' comments.

John Langdon Down

SIR: Recently, while researching 19th century methods of disposal of the dead, I visited Woking Crematorium, the oldest in Britain. I was invited into the boardroom in order to study the death certificate of the first person to be cremated at Woking. Mrs Jeannette Caroline Pickersgill of Regent's Park died, aged 71, of broncho-pneumonia and asthema (*sic*) in March 1885. The certifying doctor was John Langdon Down, who was in private practice in Harley Street at the time. This eminent Victorian, one-time Medical Superintendent of Earlswood Asylum for Idiots, founder of Normansfield Mental Hospital, who has been credited with a description of Frohlich's syndrome 40 years before Frohlich, and who is best remembered for giving his name to Down's syndrome, also earned himself a small but honourable mention in the history of cremation.

A HUNDRED YEARS AGO

Mental overwork treated by issues

Dr A. P. Langeveld, writing in the *Weekblad van het Nederlandsch Tidjdschrift voor Geneeskunde* on functional affections of the brain and spinal cord, mentions the case of a schoolmaster who was suffering from mental overwork. He complained of a painful sensation of pressure in the head and along the spine. He could not speak for five minutes or walk more than a few steps, and could scarcely read or write. Cold douches, a seton in the arm, mental rest, iodide of potassium, arsenic, and aromatic sulphuric acid producing no improvement, the writer remembered the anatomical connections of the spinal veins, and considered that a congested condition of these might very easily produce cerebral and spinal troubles. The connection of these veins with those on the surface has been pointed out by Breschet. A large blister was applied near the sacrum, and kept open by antimonial ointment, and a week later a second similar blister was applied near the first. It was interesting to mark the diminution of the pain in the head and back as the consequence of the very painful sacral sores. The mental condition began slowly to improve, but when any attempt was made to discontinue the irritant ointment it immediately became worse again. After a time, as the sacral sores were very deep, two issues were applied near the left scapula. After a considerable time the patient was able to take exercise, and ultimately to resume his occupation. The sores were healed by iodoform vaseline.

Book Reviews

Editor: Sydney Crown

Research Paradigms in Psychosomatic Medicine. Edited by G. A. Fava and T. N. Wise. Basel: S. Karger A. G. 1987. 272 pp. SFr 175, US$97.25, £79.60.

This volume will be of wide appeal. It gathers together critical reviews of a variety of research procedures and gives a series of updated reviews on recent research.

There is a general introduction on methodological issues in psychosomatic research, contributed by the editors, then four chapters on life events, the quantification of psychological stress, rating scales of anxiety and depression, and personality assessment. The latter chapter brings some order and hope to a subject bedevilled by decades of lurching from subjectivism to superficial objectivity and back again.

A chapter on behavioural assessment, using pain as an example, gives a behavioural analysis of diagnosis and treatment which can be applied to a variety of somatic problems. Another contributor describes a variety of measures that can be applied to somatisation and abnormal illness behaviour.

The vexed issue of body image in eating disorders is discussed. There is a masterly review of the psychophysiological approach that has promised so much and, with increasingly refined instrumentation, continues to have promise for the future.

The chapter on neuropsychology is a delight. Mirsky & Duncan emphasise that it is the way in which the subject goes about the test that is relevant rather than the final score, and this approach requires a high degree of training in the psychologist.

Holsboer's "Psychoendocrine strategies" is outstanding. It is devoted largely to a description of the hypothalamic pituitary adrenal axis in affective illness and the direct effects of steroids on neurological function. There is some fascinating material on the possible direct effect of corticotrophin-releasing hormone and ACTH on cerebral function, and an analysis of the effects of endocrines on the immune system and the effects of the immune system on cerebral functions through the release of peripherally produced hormones and peptides, an area of interaction which would seem most fruitful for understanding psychosomatic inter-relations. The theme is continued in a chapter on "Mind and immunity". A final chapter makes out a lawyer's case that anorexia nervosa and depressive illness have much in common.

This is a very rich feast at a very rich price. Despite the diverse nationalities of the authors, the text throughout is written in a very elegant style of English, although a remarkable number of spelling errors have slipped through. The chapters on questionnaires overlap considerably in their discussions of reliability and validity, and some pruning or cross-reference would have been helpful. It is irritating that different systems of referencing are used for different chapters.

I would encourage everyone interested in this field to read this volume – however much they may know about some of the issues discussed, the range is so great that the reader is bound to learn much that he did not know before.

Oscar W. Hill, *Consultant Psychiatrist, The Middlesex Hospital, London*

Integrated Family Therapy: A Problem-centred Psychodynamic Approach. By David Will and Robert M. Wrate. London: Tavistock. 1985. 161 pp. £17.95 (hb), £7.95 (pb)

This brief book, supported by a foreword from Nathan Epstein, is the best introduction I know to the practice of family therapy. The field can be bewildering for beginners because of the wide range of theories and methods applied, each with its eloquent exponents, but with so far little research-based evidence for the validity of the underlying ideas or the efficacy of the particular technique of intervention. The authors, both adolescent psychiatrists and also teachers at the Scottish Institute of Human Relations, note the evangelicism that persists in the family therapy literature and that often prevents students from integrating what is helpful in the different models ("... the prosetylising phase of family therapy development has encouraged therapists to practice exclusively one particular approach ..."). Their book aims to remedy this.

Will & Wrate integrate three models: the active approaches of the McMaster, problem-centred school (experiential and insight-oriented); Minuchin's structural family therapy; and psychoanalytic understanding of family transactions and of the complexities of individual's inner lives. Their's is an "open, directive approach" in which, in contrast to strategic methods, there is mutual collaboration with the family in exploring, understanding, and resolving the family's problems. The unacknowledged role of psychodynamic understanding in many family therapy interventions is stressed, as is the gap between what therapists say and what they do. This, too, the authors aim to overcome.

The stages of therapy are listed and the executive skills of therapists discussed in detail. The book ends with a helpful outline for a family therapy training programme, and a chapter on research.

I note only two shortcomings. Firstly, there is no mention of families with young children. The special skills needed to help pre-school and early school-aged children participate in therapeutic family transactions, and trainees and parents to facilitate and understand the significance of play, are not described. Secondly, and this is related to the somewhat sketchy account of family therapy research, there is little discussion of the indications for or against family therapy, as compared with other treatment interventions.

This attractive book is written clearly and enlivened throughout by case histories and brief clinical examples. Everyone concerned with the practice of child and adolescent psychiatry should read it.

SULA WOLFE, *Honorary Fellow, University of Edinburgh Department of Psychiatry*

The Medical Basis of Psychiatry. Edited by G. WINOKUR and P. J. CLAYTON. Philadelphia: Balliere Tindall. 1986. 599 pp. £49.50.

The notion of constructing a textbook of psychiatry on the basis of treating psychiatric problems as analogous to other medical problems, defining psychiatric illness as a medical illness with major emotional and behavioural aspects, and presenting the material in the familiar pattern of definition, epidemiology, signs and symptoms, aetiology, treatment, and differential diagnosis, although commonplace to British psychiatrists, is positively revolutionary in the USA and reflects the increasing ascendency of biological psychiatry in that country. Nevertheless, the contributors to this volume by no means neglect the psychosocial and psychotherapeutic aspects of the various disorders included.

Thirty-seven of America's most prestigious psychiatrists have combined to produce an uncommonly fine textbook. Each chapter is a well-referenced and up-to-date review of its subject, often supplemented by brief, but cogent, editorial interpolations. The contents are organised into four sections; 17 chapters on adult syndromes, covering the usual range of conditions, 4 chapters on child psychiatry, covering conduct disorders and hyperactivity, major affective disorders, infantile autism and schizophrenia in childhood, and emotional disorders; 7 chapters on symptom clusters; and 5 chapters on special areas. Included in this last group are the neurobiological basis of psychiatric illness, genetics of psychiatric disorders, use of the laboratory in psychiatry, epidemiology of psychiatric illness, and suicide and attempted suicide.

The entire contents are of a consistently high standard and it is difficult to select any chapters as being of particular distinction. Reflecting my own interests, I found the chapters on organic brain syndromes presenting with little or no cognitive impairment (Popkin), schizophrenia (Tsuang & Loyd) and special and unusual psychiatric syndromes (Nasrallah) to be particularly noteworthy for their lucidity and topicality.

The book is recommended both as a useful revision primer for the trainee and as a comprehensive reference work for the mature practitioner. Its expense is commensurate with its size and excellent presentation.

KENNETH DAVISON, *Consultant Psychiatrist, Newcastle General Hospital*

Between Give and Take: A Clinical Guide to Contextual Therapy. By I. BOSZORMENYI-NAGY and B. R. KRANSER. New York: Brunner/Mazel. 1986. 432 pp. $35.00.

Boszormenyi-Nagy, one of the founders of the family therapy movement, has, over a period of forty years, developed an approach called 'contextual therapy'. In this book he and his co-worker elaborate the principles and practice of the method.

The distinctive concept of contextual therapy, 'relational reality', amplifies and applies Martin Buber's notion of 'genuine dialogue'. Dialogue means mutual commitment: a trustworthy relationship in which relating partners have responsible concern for the validity of each other's interest. Four basic dimensions of relational reality guide the therapist in assessment and treatment: *factual predeterminants*, e.g. poverty or child abuse; *individual psychology*, using concepts of individuation and differentiation greatly influenced by Erickson's work and by object relations theory; *patterns of transaction and power*, drawing upon systems theory; and *'relational ethics'*. The latter fundamental ethical dimension, stating the obligation to achieve a 'fair give and take', involves such questions as what a person owes, deserves, and needs in significant relationships. The authors claim that an enhanced personal freedom derives from 'entitlement' which, earned through offering care, flows from the resolve to accept active and personal responsibility for the consequences of 'relational reality'. That responsibility extends to generations as yet unborn.

The focus of therapy is on the balance of fair exchanges between 'individual members in their close relatedness', rather than on the family. The family therapist needs to practice 'multi-directed partiality', i.e. a 'sequential siding' with each member – very different from collusion – while being accountable to all, including absent members. An important chapter stresses the necessity for the therapist to realise his own relational reality.

The contextual approach is highly optimistic. Rather than focusing on pathology, the aim is to tap residual resources of trustworthiness in close relationships, however sterile and destructive they may appear to be.

This overlong book is wordy, repetititious, diffuse, and replete with difficult and sometimes nebulous concepts such as 'intrinsic relational tribunal' and 'rejunction'. Nevertheless, it has much to offer a patient reader, not least the verbatim transcripts of clinical sessions. Its major contribution is the thought-provoking insistence on the importance of ethical choice in the process and context of psychotherapy.

ROBERT F. HOBSON, *Reader in Psychotherapy, University of Manchester*

Decline and Fall of the Freudian Empire. By HANS EYSENCK. Middlesex: Penguin Books. 1985. 224 pp. £3.95.

It has become fashionable over recent years among those who are unconvinced of the value of psychoanalysis to follow Karl Popper and pronounce it irrefutable, thereby denying it scientific status but allowing it some epistemological significance. Eysenck will give no such escape route for Freud, his ideas, or psychoanalysis. For him, psychoanalysis should be taken as a science in that it puts forward testable hypotheses which can be refuted, and he is satisfied that they have been. Furthermore, he sees it as not only bogus but dangerous.

For anyone who wants to take psychoanalysis seriously there are some very worrying and perplexing things about Freud, the theories that have developed from his work, and the clinical practice deriving from it. Eysenck identifies some of these and begins to build an effective attack in his usual compelling style. However, his purpose emerges as annihilatory rather than constructive, and because of that the book is seriously weakened. To anyone with first-hand experience of psychoanalytic practice, the latter is unrecognisable in the way it emerges as the book proceeds. When he is likening it to prostitution, warning readers never to trust anything that analysts say, comparing it to Marxism (it used to be National Socialism), or describing those who use it with difficult clients as simply requiring to feel powerful, then he really loses credibility. He is careful to say that psychoanalysis has never been fully accepted by academics or the scientific community, and suggests that it is only a minority of the older generation of American and British psychiatrists who remain committed and that these will be eroded as a newer, fresher generation take their place. I don't see much scientific rigour in putting that picture forward, although it certainly could take in people who are not familiar with the amount of training in psychodynamic psychotherapy, use of psychoanalytic models, and treatment procedures going on in British psychiatry and allied disciplines in the 1980s. I would suggest that in this country one can see and welcome a diminuation in the use of psychoanalytic theory as a popular quasi-philosophical 'catch all', accompanied by an increase, albeit as yet insufficient, in the critical evaluation of psychoanalysis as a clinical method.

I have no doubt that the book will be music to the ears of those who want to see psychoanalysis dead and buried, but for those working alongside professional colleagues of all disciplines actually in the field of patient care what has really declined is the interest in this kind of 'bee-in-the-bonnet' approach to scientific disagreements. This is particularly true of the younger generation of clinical behaviourists who are refreshingly open-minded and keenly critical. They are no more ready to take Eysenck for granted than they are Freud, however loudly they may buzz.

P. L. G. GALLWEY, *Consultant Forensic Psychiatrist, St George's Hospital, London*

The Sociopathic Personality. By BENJAMIN B. WOLMAN. New York: Brunner/Mazel. 1987. 202 pp. $25.00.

This is a rather muddled book which attempts an overview of all kinds of deviant behaviour in comparison with or in relation to sociopathic (which the author equates with psychopathic) behaviour. Thus brief paragraphs on alcoholism, drug addiction, the moral crisis, criminal violence, dictators and fanatics, etc. all appear under a series of sub-headings. Sometimes the subject matter is repeated in another part of the book.

Many paragraphs start in the same way: "Not all alcoholics are sociopaths and not all sociopaths are alcoholics but...", "Not all sociopaths are violent and not all violent people are sociopaths...", "Not all anti-social and self-righteous individuals are sociopaths but...". There are sweeping statements which research does not uphold, for example: "They plan to commit suicide but they never do it" and "All sociopaths I have seen were hypochondriacs".

The style is anecdotal in the main, mixed up with reviews of some of the established literature and references to more obscure papers. The reviews, however, are presented too briefly to impart the full message, and are wholly uncritical, so that unless one already knows the literature it is difficult to sort the worthwhile from the worthless.

The author wanders frequently into personal statements about the political arena, in particular the persecutions of the Nazi regime ("The Nazis were aggressive-sadistic psychopaths"). Nixon and Khomeini are both mentioned, as are terrorist gangs, the decline in moral standards, and the need to give young people today more purpose in life.

The only two references I tried to follow up were incorrectly indexed, and the subject index is rather sparse.

It is, therefore, a sadly disappointing book. The author clearly has had long personal experience of sociopathic patients, but the material is presented in such an undisciplined and idiosyncratic way as to detract from or obscure its potential for contributing to our knowledge of this subject.

J. STUART WHITELEY, *Consultant Psychiatrist and Medical Director, Henderson Hospital, Surrey*

Sexual Aversion, Sexual Phobias and Panic Disorders. By HELEN S. KAPLAN and DONALD F. KLEIN. 1987. 166 pp. $25.00.

Sexual avoidance disorders may form a spectrum from sexual aversion, through sexual phobia, to panic. Despite the authors' distinction, their book might strike therapists on this side of the Atlantic either as repetition of what is known by most sex therapists or, in its plea for the use of psychotropics, unproven. Kaplan offers guidance in the assessment and management of sexual avoidance disorders, with the management emphasising, as is customary now, psychodynamic, cognitive, and behavioural aspects. The 'new' aspect they emphasise is the additional use of tricyclic antidepressants in the treatment of the panic disorders. No objective data is offered in support, and the notion that psychotropic medication is likely to be helpful with these problems may bring a wry smile to the face of many sex therapists.

Clinical case descriptions are supplied, but the whole book gives the impression of being composed too rapidly, so that it is poorly thought out both conceptually and in presentation. Only the authors' reputation will ensure that departments buy this book.

SIDNEY CROWN, *Consultant Psychiatrist, The London Hospital*

A Decade of Progress in Primary Prevention. Edited by MARK KESSLER and STEPHEN E. GOLDSTON. Hanover: University Press of New England. 1986. 424 pp. £18 (pb), £28 (hb).

The contents of this book were initially presented as papers at the Vermont conference on the primary prevention of psychopathology, held in 1984. This marked a decade since the first conference, and provided an opportunity to review and reassess the past and look to and give direction for the future.

The publication is divided into five parts. The first is a review by Professor E. L. Cowen of Rochester University, which looks at recent accomplishments in the field of prevention and star-gazes in regard to future developments. He supports both person-centred strategies (i.e. development of interventions enhancing people's ability to adapt and deal with stress) and systems-level strategies (which diminish stress sources and develop people's opportunities).

The second part looks at research, including the fields of psychiatric genetics, social stress, risk factors for schizophrenia and other psychological disorders, child psychiatric development and developmental epidemiology studies (which provide the basis for specific preventive interventions). There is also a review of the literature on infant mental health. It is now possible to identify and deal with at-risk behaviour in infancy, although more work needs to be directed at the most effective early intervention.

The third part consists of reports of results from prevention projects that have been undertaken and further ideas for developing more. Work is presented focusing on the element of constituent validation, i.e. ensuring that the programme makes sense to the people who are going to use and benefit from it, which is so necessary for the activities to continue after the researchers leave.

The next chapter in this section is by Professor Caplan, concerning crisis intervention and support services promotion. He discusses a model of primary prevention and illustrates case work with adults and children facing the stress of surgery or death. Other topics in this section include public education and communicating information, self-help organisations, and education involving professionals for prevention.

The fourth section deals with the politics of primary prevention, with a resumé of the supporters and adversaries in the American scene. The state-backed programmes, the national prevention policy, and the Federal viewpoint with the role of the National Institute of Mental Health are also outlined.

The fifth and final part is a summary attempting to bring together the varying themes and aspirations for the future.

The multiple prospectives of primary prevention of psychopathology presented in this book as a result of papers delivered at a conference have been packaged in a style of variable appeal. The keen observer of this speciality will find some aspects of this book of some interest, if he or she is patient enough to overcome the rather lengthy and verbose sections.

SIMON M. WISEMAN, *Clinical Lecturer, Whittington Hospital, London.*

The Psychology of Pain (2nd ed.). Edited by RICHARD A. STERNBACH. New York: Raven Press. 1986. 255 pp. $34.00.

Sternbach is a pioneer in the assessment and treatment of pain maintained by psychological mechanisms. The first edition of *The Psychology of Pain* (1978) has been widely read. In the second edition, with the same authors, advances can be seen. In addition to psychology there are chapters on neurophysiology, neurochemical processes, hypnosis, and psychiatric aspects of pain. Authors include Craig, Chapman, Fordyce, Melzack, Merskey, and Pilowsky, as well as Sternbach.

This book is recommended for all those working with chronic pain who wish to understand more about the psychological, neurophysiological, and psychiatric mechanisms involved. The layout and printing are better than the first edition and the book is good value for money.

STEPHEN P. TYRER, *Consultant Psychiatrist, Royal Victoria Infirmary, Newcastle upon Tyne.*

Countertransference. Edited by HERBERT S. STREAN. New York: The Haworth Press. 1987. 131 pp. $22.95.

Did Freud wear blue jeans, snap his fingers, and chew gum? If so, perhaps he really did issue the "famous" injunction to psychoanalysts which Reuben Fine tells us about: "Keep cool, don't let yourself get involved".

Current issues in Psychoanalytic Practice, Volume 2, Numbers 3 and 4 have been put between hard covers. The book consists of a collection of papers of dubious quality and little originality. It is probably of some use to students of psychotherapy who wish to familiarise themselves with the clinical issues and has bibliographic value for those preparing review articles.

STEPHEN WILSON, *Consultant Psychiatrist/Psychotherapist, Littlemore Hospital, Oxford*

Psychiatric Polarities: Methodology and Practice. By PHILLIP R. SLAVNEY and PAUL R. MCHUGH. Baltimore: The John Hopkins University Press. 1987. 136 pp. £13.75.

In this book the authors consider certain theoretical issues in psychiatry, following their previous work *The Perspectives of Psychiatry,* published in 1983, which examined the basic types of approach characteristic of psychiatry. The issues considered in the present book concern, as the title suggests, dichotomies in psychiatry. The basic dichotomy, the authors suggest, is that between the mind and the brain. The former connotes subjective experience, inner realities, meaning, and so forth; the latter is objectively observable, subject-matter of the sciences, operating (one supposes) according to causal principles. The polarity between these two kinds of phenomena, the unassailable legitimacy of each, means that psychiatry inevitably comprises an ambiguity. It will always have to learn, for example, both from the natural sciences and from the humanities. This basic polarity gives rise to others, which are discussed in turn. These include the contrast between Hebraic and Hellenic conceptions of man (roughly, emphasis on the individual compared with on generalities) and aspects of the physician-patient relationship, e.g. whether it should be 'contractual' or otherwise, 'paternalistic' or otherwise, etc.

Arguably the authors have too simple a view of the mind/brain dichotomy, and they stretch the sense in which other polarities presuppose it. But in fact these weaknesses, if such they be, detract little from the book, for what it achieves is clear presentation of some major issues in psychiatry, which do indeed often have the form of either/or dichotomies. The authors bring out what lies behind each side of the conflict, and show that extreme general claims are less useful than detailed consideration of particular cases or kinds of case. The book is an excellent introduction to the issues and probably an excellent antidote to (premature) dogmatism. It is especially recommended to the beginner.

DEREK BOLTON, *Senior Lecturer, Institute of Psychiatry, London*

Hysteria and Related Mental Disorders: An approach to Psychological Medicine (2nd edn). By WILFRED D. ABSE. Bristol: Wright. 1987. 466 pp. £70.00.

The first edition of this book was based on the wartime experience of Abse as a military psychiatrist in the UK and in India. The present edition represents a considerable revision which, according to the author, explores the nature of disturbances of consciousness, ego, and psychology and its increasing forensic relevance. Linguistic development, dissociation, and the recent notions of splitting are all examined. The text is nearly twice as long as that of the first edition. The price in 1966, for comparison, was 42 shillings.

Abse writes clearly. The material he presents is analyzed partly in traditional terms relating to symptoms which are accepted as hysterical, and partly in terms of current psychoanalytic thought. The original Freudian ideas are also described in considerable detail. A large number of clinical histories are presented, and Abse clearly has a good deal of skill in interviewing patients with profound difficulties and in improving their relationships and adjustment. There are several drawbacks, however. Important material which should figure in any serious discussion of hysteria is neglected. For example, the work of Slater, Trimble, and Roy does not appear, and hypnosis is considered without reference to Barber. The systematic data, which shows that there is a relationship between hysteria and sexual difficulty in some cases of the former, but not in all, is ignored, and problems of potency are assumed automatically to be hysterical when due to a psychological cause. Epilepsy is treated as a manifestation of a primary process, and protracted vaginismus is said, without evidence, to be connected with repressed, sadistic impulses such as revenge upon the penis and the man. Phobias are treated in one place as hysteria (page 107). Dissociation in different states, such as hysteria and schizophrenia, is taken to be the same, which is not known. The Ganser and Munchausen syndromes are described inadequately, even omitting some of the most helpful psychoanalytic views on the latter, and the syndrome of Gilles de la Tourette is placidly accepted as a psychological disorder, despite mention of the use of haloperidol. The dynamic interpretation of cases, in its most far-reaching form, is presented in an assured fashion without any sort of meaningful proof. Complex and peculiar hypotheses are maintained at a great remove from factual data.

Altogether, the book relies on authority more than proof and does not present a balanced account.

HAROLD MERSKEY, *Director of Education and Research, London Psychiatric Hospital, London, Canada*

Affective Disorders in the Elderly. Edited by ELAINE MURPHY. Edinburgh: Churchill Livingston. 1986. 235 pp. £28.00.

This book is concerned with arguably the most important group of mental disorders to afflict the elderly, for while affective illnesses are amenable to treatment, too often they relapse and generate states of chronic invalidity.

Murphy has assembled 16 authors who between them contribute 14 chapters. Three are devoted to therapies covering psychological, physical, and drug treatments. That on psychological approaches is informative, well balanced, and extremely helpful; that on physical treatment is competent; that on drugs tells us little that is new and often assumes that simple therapies are likely to succeed in the majority of cases.

Chapters on biological and social factors in causation are each well written, but one on the relationship between physical illness and depression tends to cloud rather than clarify issues, with close inspection of the trees obscuring the forest of evidence that if you want to stay happy in old age, you should avoid major physical ill-health.

A chapter on course and outcome is presented with customary clarity of thought by Felix Post, who reviews recent evidence as well as his own definitive studies. A chapter on suicide gets my vote (and that of my Senior Registrar) for being "best contribution by any author" for not only assembling interesting facts, but drawing attention to aspects of suicide prevention.

The affective disorders of mania and the anxiety states are allocated a chapter each. The first is a model of information and coherent presentation, the second largely 'waffle' but with some helpful hints on treatment. Sketchy reviews of Freud's changing theories as to the causation of the psychoneuroses are not needed in this setting.

The distribution of affective disorder is well presented by Swartz & Blazer and the editor's obligatory 'concept' chapter is happily brief and to the point. Finally, there is a solidly competent chapter on characteristics (clinical features) and a rather better one on managing the depressed elderly person at home, addressed primarily to the general practitioner.

I started this book with a feeling of keen anticipation, and put it down feeling rather disappointed. As there are many excellent contributions therein, some explanation is necessary. There is far too little emphasis on the management of the difficult and frequently relapsing case, and I would have preferred a chapter devoted entirely to this topic. Again, some contributors padded out their offerings with data more appropriate to general psychiatry, and generated the suspicion that they were lacking in specialist knowledge. These deficiencies spoilt an otherwise good book.

GARRY BLESSED, *Consultant in the Psychiatry of Old Age, Newcastle General Hospital, Newcastle-upon-Tyne*

Psychological Trauma. By BESSEL A. VAN DER KOLK. Washington: American Psychiatric Press. 1987. 237 pp. $25.00.

The book aims to explore the human response to traumatic events – those that "overwhelm both psychological and biological coping mechanisms." The intention is to present a "general theory of the human trauma response". The author is Director of the Trauma Centre, Harvard Medical School. He argues that psychological damage resulting from uncontrollable terrifying life events has been relatively neglected in the past 70 years but that interest has revived following the Vietnam War, so that post-traumatic stress disorder (PTSD) has appeared in DSM–III. His approach is construed as psychobiological.

Features of PTSD are described and related theories briefly reviewed. The review also encompasses the experiencing of trauma by children, the Chowchilla kidnapping, and physical and sexual abuse.

The essence of the trauma response is seen to be the severance of affiliative bonds. The author's ideas are developed in relation to attachment theory and research into biological correlates of affiliative behaviour and the disruption of attachment. PTSD is argued to be associated with the loss of the ability to modulate arousal: traumatic events induce a biological vulnerability linked to endogenous opioid systems.

The scope of the book is evidenced by chapters on the effect of abuse on children's thought, trauma in the family, and on group, individual, and stress management orientations to treatment.

A book which draws attention to PTSD is welcome, but the theorising often seems loose and undiscriminating and the review of related research uncritical. European research related to the two World Wars is neglected. The approaches to treatment described are interesting and eclectic. It must be hoped that a more usefully articulated theory will evolve in due course.

ANTONY D. COX, *Professor of Child & Adolescent Psychiatry, Royal Liverpool Children's Hospitals*

Antimanics, Anticonvulsants and Other Drugs in Psychiatry. Edited by GRAHAM D. BURROWS, TREVOR R. NORMAN and BRIAN DAVIES. Amsterdam: Elsevier. 1987. 451 pp. US $133.35, Dfl. 300.00.

This is the last of a series of four handbooks, and contains a useful mixture in which patients and the clinical aspects of their management are to the forefront. Ample space is given to novel information, reviews, summaries, and conclusions which can be appreciated irrespective of the preceding volumes. The first four chapters consider the current status of lithium, carbamazepine, and antipsychotic drugs in the treatment of hypomania and mania. The specific advice given for clinical situations is particularly helpful. Intermediate chapters give a detailed appraisal of anticonvulsants, including their use in the mentally handicapped and in pregnancy. Pseudoseizures, and the effect of anticonvulsants on affect and cognition, are well reviewed. Anticholinergic drugs, beta-blockers in schizophrenia and in anxiety, and the effects of cortico-steroids and of oral contraceptives are all discussed in detail.

The latter half of the book also has a clinical leaning, dealing with tic disorders, Huntington's chorea, and Parkinsonism, but the focus returns to drugs used in phobic disorders, in alcoholism, and in the treatment of dementia. The role of analgesics and psychotropic drugs in pain management is clearly outlined. The concluding chapters cover sexual dysfunction, psychiatric reactions to non-psychotropic drugs, and the issue of compliance.

The style and format make comfortable reading and, matching the content, the print and finish of the book reach the highest standards. It would be difficult to find a better guide to the therapeutic areas described here. The book provides liberally the sort of information essential for broad clinical practice and needed frequently in liaison work in a District General Hospital.

JOHN POLLITT, *Consultant Physician in Psychological Medicine, Hayes Grove Priory Hospital, Kent*

Stress Response Syndromes (2nd edn). By MARDI JON HOROWITZ, Northvale, NJ: Jason Aronson. 1986. 358 pp. $35.00.

This is an important book on an important subject. It fully deserves its second edition within 8 years of publication. Post-traumatic stress disorders are, sadly, increasingly relevant in psychiatry as society becomes both more violent and more caring. This book is at one level a primer on psychotherapeutic help for victims of trauma – by rape, sudden bereavement, or injury. It describes with great sensitivity and detail the feelings of fear, rage, shame, guilt, and numbness associated with trauma and focuses in particular on 'intrusive images' of violence that can haunt victims for years afterwards. It shows how, if these feelings are to be overcome, the meaning of the trauma in the patient's biography has to be understood; how, for example, a man with violent fantasies towards women will be doubly traumatised when a female passenger in his car is killed; or a woman who deals with low self-esteem by flirting may be plagued with shame following rape; or how a teenage girl will be devastated if her mother dies of a heart attack just after they have had a blazing row. The twin dangers faced by trauma victims are described: either emotional shut-down or being flooded with unmanageable feelings. It shows how, in the safety of a psychotherapy session, psychological controls can be relaxed enough for painful feelings to be contemplated and for psychological reintegration to occur. It demonstrates the great tact that is needed to decide when to offer support and sympathy and when to probe, and how different personality styles demand different approaches.

This book has many other important levels. Horowitz is that rare phenomenon: someone who is equally respected as a psychoanalyst and a researcher. As well as being a clinical treasure chest, the book also contains an elegant outcome study showing the efficacy of twelve-session brief psychoanalytic therapy in stress disorders, a scholarly review of Freudian theory on trauma, and an important integrated psychoanalytic/cognitive theoretical schema. Despite occasional verbosity it is very readable. It is an exemplary book, which all who are interested in applied psychotherapy should read.

JEREMY HOLMES, *Consultant Psychiatrist, North Devon District Hospital, Devon*

Key cases in Psychotherapy. Edited by WINDY DRYDEN. Beckenham: Croom Helm. 1987. 269 pp. £22.50.

It is difficult to do justice to this book in a short review. The editor's aim has been to show how therapists working with the benefits and limitations of their different schools of thought and practice grapple with patients who challenge their underlying assumptions and become instrumental in changing therapists' theory and practice.

Wessler, Lazarus, Prochaska and Ellis's experiences have been well integrated, and stimulate considerable interest. Thorne and Rowan arouse the anxieties they themselves felt over the risks taken when therapy moved into unchartered waters. Morrison, Aveline, Wile, Butt and Bannister each demonstrate their own significant lessons. Some contributions, however, may confuse the novice or irritate the experienced therapist. Prospective readers should taste a little of each contribution before making a final decision to buy.

BRIAN LAKE, *Honorary Lecturer, University of Leeds*

Contents of
THE AMERICAN JOURNAL OF PSYCHIATRY

THE BRITISH JOURNAL OF PSYCHIATRY

December 1987 Vol 151

Published by
The Royal College of Psychiatrist

ISSN 0007–1250

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al*, *British Medical Journal*, 7 May 1983, **286**, 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that . . . '

DURKHEIM, E. (1897) Le Suicide. Paris. Translated (1952) as Suicide: A Study in Sociology, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. British Journal of Psychiatry, **124**, 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970) Education, Health and Behaviour. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In Pathology and Treatment of Sexual Deviation (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

Mental Health Foundation

Career Development Fellowships
for
Research Into Mental Disorders

Applications are invited from medical and scientific graduates for a Fellowship for research training in the field of mental disorder.

These awards which are tenable for up to 3 years, are intended for clinicians with a training in psychiatry or intending to train in psychiatry, or postdoctoral scientists who wish to extend their research experience. The research proposals should be relevant to mental health or related basic science and the applicant should intend to continue research in this field. These Fellowships may be held in appropriate departments or clinical centres in Great Britain. The Trustees are prepared to consider a request that part of the Fellowship be spent in a suitable centre, or centres, abroad in cases where the necessary research training cannot all be obtained in Great Britain. Candidates are welcome to discuss their plans with the Honorary Secretary of the Research Committee.

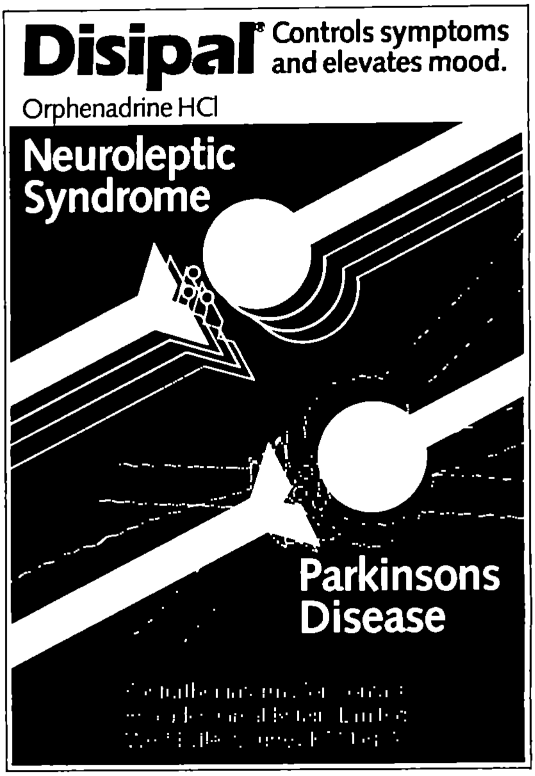
Candidates should not normally be over 32 years of age for science graduates and 34 years for medical graduates. However, consideration will be given to those over this age where their career has been affected either by a late start or by interruption for personal/family reasons. Applications should be made jointly with the head of the Department in which the candidate proposes to work. Salaries will be in the range of University Lecturer or NHS Registrar scales (whichever is appropriate) according to age and experience.

Application forms can be obtained by *writing* to

The Secretary of the Research Committee
The Mental Health Foundation
8, Hallam Street, London W1N 6DH

APPLICATIONS MUST BE RETURNED BY MARCH 1st

(*Late applications will not be considered*)



PSYCHIATRISTS

Immediate openings available at the Veterans Administration Medical Center, Lebanon, Pennsylvania, U.S.A.

Candidates who are eligible for American Board Certification preferred.

Located in beautiful south central Pennsylvania, home of the Pennsylvania Amish. Low cost of living yet near urban centers for cultural enrichment. G M & S Facility with large psychiatric service and outpatient clientele. Competitive salaries with excellent vacation, retirement system, and other fringe benefits. Equal Opportunity Employer.

Announcing the new DSM III R

NEW FEATURES

- Diagnostic criteria revised throughout to be clearer and more clinically useful
- Greatly expanded section on substance abuse
- New classification and criteria for the sleep disorders
- The Multi-Axial System has been revised
- Revised decision trees
- Entire text redesigned for easier reference:
  - criteria clearly set off with bold headings
  - running heads at top of page
  - page numbers triple referenced in the classification, table of contents and index
  - individual criteria in alphabetical order within major classifications wherever possible

Diagnostic and Statistical Manual of Mental Disorders

Third Edition Revised

AMERICAN PSYCHIATRIC ASSOCIATION

The entire text of the highly successful DSM III has been revised to take account of the latest data available for the consideration of associated features, the course, complications, prevalence, differential diagnosis and other factors that influence the diagnosis of mental disorders. In particular the diagnostic criteria have been revised, there is a new classification and criteria for sleep disorders, and a greatly expanded section on substance abuse. The book has been redesigned to make it easier to use, with many useful features incorporated.

567 pp. *0 521 34509 X* **Hc £35.00 net**

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

FORGE HOUSE ROMSEY

A new residential nursing home for the treatment of Alcoholism will open on December 1st 1987. Full 24 hour nursing facilities with resident staff and expert counselling.

All enquiries to the Medical Director at Romsey (0794) 388385.

NOW AVAILABLE PROCEEDINGS OF THE SCHIZOPHRENIA CONFERENCE

Held in the Spring of 1986 at Edmonton.

A comprehensive look at the ethical, legal, social and familial impact of Schizophrenia. This attractive volume will be of interest to:

Educators
Families of Schizophrenics
Mental Health Professionals
Legislators
Physicians
Administrators of Services for the Mentally Ill

KEEP FULLY INFORMED

Books for Psychiatrists from Churchill Livingstone

AFFECTIVE DISORDERS IN THE ELDERLY

(Medicine in Old Age)

Edited by E. Murphy

1986 235 pages illus cased
£28.00

A comprehensive account of the epidemiology, symptomatology, aetiological factors and management of affective disorders in old age. Covers depression in particular detail, but also discusses anxiety disorders, mania and bipolar affective disorders.

"There is a great deal to be learned from these pages and a great deal to stimulate further thinking ... this is a worthwhile collection that will be read widely" *Postgraduate Medical Journal*

DEMENTIA

(Medicine in Old Age)

Edited by B. Pitt

1987 346 pages illus cased
£40.00

This important new work provides a comprehensive, authoritative and up-to-date statement of present knowledge on dementia. Covers both the *nature* of dementia—its manifestations, prevalence, pathology and aetiology, and its *treatment*.

RECENT ADVANCES IN CLINICAL PSYCHIATRY-5

Edited by K. Granville-Grossman

1985 288 pages illus cased
£24.00

"... essential reading for trainees and senior psychiatrists ..."
The British Journal of Psychiatry

RECENT ADVANCES IN PSYCHOGERIATRICS-1

Edited by T. Arie

1985 248 pages illus cased
£32.00

"... The topics are relevant and the literature surveyed contemporary ... Many of the contributors have made significant advances in research and practice and they write with authority ..."
British Journal of Psychiatry

PSYCHIATRIC DIFFERENTIAL DIAGNOSIS

J. M. Pfeffer and G. Waldron

1987 199 pages illus
paperback £14.95

A well-organised and practical guide to the differential diagnosis of commonly presented psychiatric symptoms. Includes many case histories. Ideal for postgraduate trainees.

NEUROPSYCHOLOGICAL REHABILITATION

Edited by M. J. Meier, A. L. Benton and L. Diller

1986 520 pages illus cased
£45.00

A discussion of rehabilitation theory and practice directed towards the restoration of impaired cognitive functions in patients with brain injury and disease.

ALZHEIMER'S DISEASE AND RELATED DISORDERS

(British Medical Bulletin Volume 42 No 1)

Edited by Sir M. Roth and L. L. Iversen

1986 116 pages illus
paperback £20.00

"... Summarises the work of the last ten years ... a publication for obligatory reading" *Age and Ageing*

MENTAL HEALTH AND THE ENVIRONMENT

Edited by H. L. Freeman

1985 500 pages illus cased
£40.00

"In bringing together so many aspects of the relationship between environment and mental well-being this welcome text succeeds to a remarkable degree ... it is arresting in its impact" *British Journal of Psychiatry*

Forthcoming ...
New edition scheduled for early 1988

COMPANION TO PSYCHIATRIC STUDIES

Edited by R. E. Kendell and A. K. Zealley

1988 Fourth edition about 800 pages illus cased

SCHOOL OF HYPNOSIS AND ADVANCED PSYCHOTHERAPY

Since 1980, SHAP has been conducting comprehensive, professional HYPNOSIS/PSYCHOTHERAPY diploma courses based on modern (Ericksonian) methods and NLP.

The courses are in 3 Parts and applications are now being considered for the next Part 1 Course which spans 5 weekends in FEB/MAR, 1988.

For 24-page prospectus and details please send large stamped addressed envelope to Registrar, SHAP, 28 Finsbury Park Road, London N4 2JX.

Mental Health Foundation

RESEARCH GRANTS

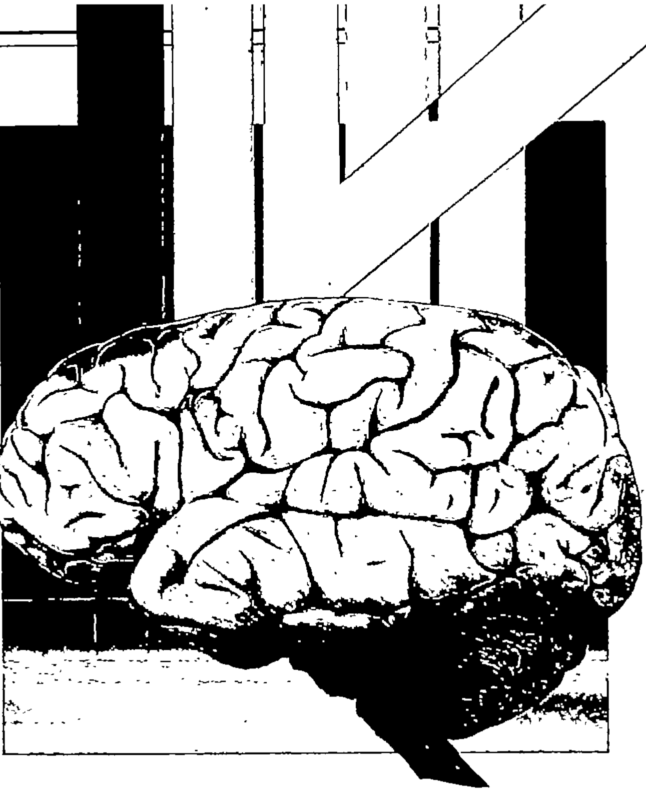
The Research Committee of the Foundation exists to foster and support research in all fields bearing on mental health, mental illness and disorders of mental development.

The Committee meets twice a year to award **RESEARCH GRANTS TO PROVIDE SCIENTIFIC ASSISTANCE, EXPENSES** or **EQUIPMENT** for research workers.

Closing Dates:
March 1st for Meeting in May
September 1st for Meeting in November

For Grant application forms and further details apply in writing to:

The Honorary Secretary,
The Research Committee,
Mental Health Foundation,
8 Hallam Street,
London W1N 6DH



The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine[1] trifluoperazine[2] and haloperidol[3] but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia[4]

sulpiride

Dolmatil™

IN SCHIZOPHRENIA

MENTAL HEALTH CARE

SQUIBB

Prescribing Information Dolmatil Tablets· Plain white round tablets with a transverse breaking line on one side and the mark D200 on the other Each tablet contain 200mg sulpiride. **Indications:** Acute and chronic schizophrenia **Dosage:** A starting dose of 400mg to 800mg daily, given as one or two tablets twice daily (morning an early evening) is recommended. **Predominantly positive symptoms**· Starting dose of at least 400mg twice daily, increasing if necessary up to 1200mg twice dai **Predominantly negative symptoms:** Starting dose of 400mg twice daily reducing as required towards 200mg twice daily **Mixed positive and negative symptom** 400mg–600mg twice daily. The same dose ranges may be required in the elderly, but should be reduced if there is evidence of renal impairment Clinical experience children under 14 years of age is insufficient to permit specific recommendations. **Contraindications:** Phaeochromocytoma **Warnings**· Extrapyramidal reaction principally akathisia have been reported in a small number of cases. If warranted, reduction in dosage or anti-Parkinsonian medication may be necessary After over decade of widespread use in many countries, tardive dyskinesia has occurred rarely, insomnia has been reported, increased motor agitation has been reported at hig dosage in a small number of patients. in aggressive, agitated or excited phases of the disease process, 'Dolmatil' may aggravate symptoms. Care should be exercise where hypomania is present Galactorrhoea, amenorrhoea and gynaecomastia may occur in association with hyperprolactinaemia. **Precautions.** Epilepsy – anti-convulsan therapy should be continued unchanged. Impaired renal function, as sulpiride is eliminated via the kidney Pregnancy – the general principle of avoiding drug treatmen during pregnancy, particularly during the first sixteen weeks, should be followed **Product Licence Number:** PL 5299/0006. **Legal category:** POM **Basic NHS cos** 63p per day at dose of 600mg daily **Name and address of Distributor:** E R Squibb & Sons Ltd, Squibb House, 141–149 Staines Road, Hounslow, Middlesex TW3 3 •Trade Marks of E R Squibb & Sons Ltd (Distributor) DOLMATIL – Trade Mark of SESIF. Authorised User Delagrange Ltd. **References** 1 Harnryd C et al Acta Psychiatr Scan 1984;69. Annotation

The Place of Benzodiazepines in Psychiatric Practice

PETER TYRER and SIOBHAN MURPHY

For the past 20 years, benzodiazepines have been the most commonly prescribed psychotropic drugs. It is now difficult to imagine the excitement produced by this new class of compounds. Existing anti-anxiety drugs, mainly the barbiturates, were known to be dangerous in overdosage, tend to cause addiction, and have many side-effects. Previous compounds, including opium, alcohol, chloral, and bromides, were similarly burdened. The benzodiazepine era began almost 30 years ago, in style. "Four hours after being given chlordiazepoxide on New Year's day 1958, one of 12 chronically anxious but therapeutically recalcitrant patients previously studied by Tobin and N. D. C. Lewis telephoned that for the first time in many years he was totally free from symptoms!" (Hordern, 1968). The early studies were all enthusiastic and confirmed the therapeutic potential of the drug (Tobin *et al*, 1960; Jenner *et al*, 1961). In the 'tranquilliser decade' of the 1970s, prescriptions of benzodiazepines increased at a rate that was perceived as alarming, 'the relentless march of the psychotropic drug juggernaut' (Trethowan, 1975). This concern was related more to the inappropriate use of these drugs for treating personal problems than to the demonstration of dangers with these compounds. The dangers, however, appeared to be remarkably few; the drugs were safe in overdose, had greater efficacy than the barbiturates (Lader *et al*, 1974), and had virtually no unwanted effects, apart from sedation when given in excessive dosage. It was therefore hardly surprising that they proved so popular with clinicians. As Priest (1980) commented when benzodiazepine prescription was at its peak: "it is a tremendous boon to the medical profession to have active weapons in the fight against misery that are not only effective but are relatively safe when abused by despairing and desperate patients".

Since this time a dark shadow has been cast over the benzodiazepines by the spectre of dependence. While it had been realised from earlier studies that dependence could be a problem (Hollister *et al*, 1961), this was thought to apply only when doses well above the therapeutic range had been used. Even with high dosage, doubt was cast upon the role of benzodiazepines in producing dependence, as in so many published reports alcohol and other addictive drugs were taken as well as benzodiazepines (Marks, 1978). As by far the larger proportion of drugs taken was for therapeutic purposes, on prescription, and, by and large, clinicians were perceived to prescribe these drugs responsibly (Mellinger *et al*, 1978), there did not seem to be much need for concern. However, the demonstration that regular treatment with benzodiazepines in therapeutic dosage could produce significant withdrawal problems when the drug was stopped (Pevnick *et al*, 1978; Tyrer, 1980; Winokur *et al*, 1980; Petursson & Lader, 1981; Tyrer *et al*, 1981, 1983) led to a change in attitudes. The wonder drugs of yesterday were now addictive and 'even worse than heroin' according to many accounts in the media. Doctors have been reviled for prescribing them and patients are now being encouraged to sue doctors for making them dependent.

The medical profession has reacted with some confusion. Some doctors (e.g. Snaith, 1984) feel that benzodiazepines no longer have a place in clinical practice, whereas others (e.g. Oswald, 1986) have gone the other way and suggest that benzodiazepine hypnotics should be available without a prescription as they are so much safer than the alternatives, particularly alcohol. It is therefore difficult for the average psychiatrist in practice to know when to prescribe benzodiazepines and how to treat the many patients who have taken benzodiazepines regularly before presenting to the psychiatric services. It is also difficult to know which benzodiazepine to prescribe, because of conflicting accounts of their advantages and dangers.

Indications for prescription

Although benzodiazepines have an important place in the treatment of epilepsy and disorders of muscle tone, most psychiatrists use them for the treatment of anxiety and insomnia. In the past, the presentation of either of these complaints at the general practitioner's surgery was often followed by the reflex prescription of a benzodiazepine, nicely summarised in Marinker's epigram "you are a case of diazepam, you had better have some anxiety" (Marinker, 1973). Nowadays all practitioners are much more circumspect about prescribing a benzodiazepine. However, in anxiety occurring at a time of major stress, now formally diagnosed as acute stress or adjustment reactions in both ICD-9 (World Health Organization, 1978) and DSM-III (American Psychiatric Association, 1980), it may be appropriate to prescribe a benzodiazepine if distress is severe and prescription is likely to be short-term.

Even for this indication, care must be taken to prescribe benzodiazepines judiciously; they produce a degree of anterograde amnesia and this could provoke the mental mechanism of denial in subjects who need to come to terms with the stressful event to achieve a satisfactory psychological adjustment. In instances such as bereavement and other major personal loss, prescription needs to be for as short a time as possible and then only to relieve the worst of the symptoms. In other forms of anxiety, benzodiazepines are much less appropriate. This includes the unfocused anxiety of anxiety neurosis and generalised anxiety disorder (in DSM-III), which is one of the commonest psychiatric disorders presenting to the general practitioner. It has been shown that relatively simple psychological treatments such as reassurance and explanation can replace benzodiazepines successfully in primary care (Catalan & Gath, 1985) and avoid the need for any psychotropic drugs. If drug treatment is needed for persistent or disabling anxiety symptoms that are not part of an adjustment or stress reaction, other drugs can be used. There is now good evidence that antidepressants are more effective than benzodiazepines in this group (Johnstone *et al*, 1980; Kahn *et al*, 1986). For many years it has been known that anxiety presenting in the form of acute panic attacks also responds better to antidepressants (Klein, 1964), and the same has also been shown with agoraphobia (McNair & Kahn, 1981).

The use of benzodiazepines in the treatment of insomnia has changed much less than that for the treatment of anxiety. It is still common practice in many psychiatric hospitals for patients to be prescribed a benzodiazepine hypnotic almost as a matter of routine. This may be appropriate if it is only given for a short time or on an occasional intermittent basis, but if it becomes regular, it can lead to continued prescription because of dependence. There is now abundant evidence that 'rebound insomnia' (Kales *et al*, 1978) occurs when a benzodiazepine hypnotic is taken for a few weeks only and then suddenly withdrawn (Kales *et al*, 1983*a*). As other problems with benzodiazepines, noticeably impairment of cognitive and psychomotor function, are less important for a hypnotic than an anti-anxiety drug, there is a belief developing that it is appropriate to give a benzodiazepine long-term for the treatment of insomnia but not for the treatment of anxiety. This is a dangerous assumption, not least because the use of benzodiazepines in the treatment of anxiety and insomnia is interchangeable, and their marketing for separate purposes is a commercial rather than a pharmacological decision. There is no reason why psychological treatments should not be used similarly for insomnia as for anxiety, and much more use should be made of intermittent drug therapy.

The other major use for benzodiazepines is in the treatment of alcohol-withdrawal reactions (Kaim *et al*, 1969). This practice has also come under closer scrutiny since benzodiazepines have been shown to produce dependence. Clearly, if one form of dependence was merely being replaced by another, the use of benzodiazepines for detoxification purposes could not be recommended. In practice, far greater attention is paid to reducing doses of benzodiazepines (and other agents) used for detoxification, so that drug treatment is withdrawn between 7 and 10 days (Thorley, 1982). This also makes good clinical sense, as alcohol-withdrawal symptoms have a short time course.

Duration of treatment

Benzodiazepines exert their therapeutic action within 60 min and reach a peak of efficacy within 2 h of administration. Tolerance to their effects develops quickly (Aranko *et al*, 1983, 1985), but is not nearly so marked as with the barbiturates and other older anti-anxiety drugs. The ideal form of treatment is intermittent flexible dosage, in which medication is taken occasionally at a time of increased symptoms but never on a regular basis (Tyrer, 1982). This may avoid the development of dependence, although hard evidence for this is lacking.

There is now good evidence that a significant proportion of patients taking long-term benzodiazepines in regular dosage develop pharmacological dependence. This is mainly manifest in the form of a withdrawal syndrome which includes the features of pre-existing anxiety together with panic, perceptual disturbances such as hypersensitivity to all sensory modalities, and depersonalisation, tinnitus, paraesthesiae, muscle pain and weakness, and, rarely, epileptic fits and schizophreniform psychoses, including first-rank symptoms of schizophrenia (Petursson & Lader, 1981; Tyrer *et al*, 1981, 1983; Busto *et al*, 1986; Roberts & Vass, 1986). This has led to greater caution in prescribing benzodiazepines for long periods, but the implied assumption from these studies is that shorter treatment for a few weeks is safe from the risk of dependence. This assumption seems to be misplaced, as there is now good evidence that regular treatment with a benzodiazepine for periods of 4–6 weeks is followed by a significant incidence of withdrawal problems if the drug is stopped suddenly after this time (Fontaine *et al*, 1984; Murphy *et al*, 1984; Power *et al*, 1985). The idea of giving a short sharp course of benzodiazepines followed by sudden withdrawal is therefore no longer considered to be an appropriate use of these compounds. If intermittent flexible dosage is not possible and regular treatment is preferred, it is wise to confine treatment to a few weeks and then to reduce the drug gradually after this period in the same way recommended for long-term use of benzodiazepines (Tyrer *et al*, 1983; Higgitt *et al*, 1985).

The psychiatrist is more frequently faced with a patient who has taken benzodiazepines for many months or years, for whom he has to make a decision whether to continue treatment. The first thing to remember is that a substantial proportion of such long-term users do not have significant problems when reducing and stopping their benzodiazepines. Studies of unselected referrals suggest that only 35–45% of long-term users have withdrawal symptoms, and over 50% can stop their medication without withdrawal problems (Tyrer *et al*, 1981, 1983). If there is no good reason for continuing prescription of a benzodiazepine, then a straightforward withdrawal regime can be adopted, determined either by the psychiatrist or by the patient to carry out in his or her own time (Tyrer, 1986).

For those who have had apparent withdrawal symptoms whenever they have reduced their benzodiazepines, the situation becomes more complicated. A range of treatments is available, including withdrawal under cover of antidepressants (Tyrer, 1985), concomitant treatment with beta-blocking drugs such as propranolol (Tyrer *et al*, 1981), and psychological aids, including relaxation training and techniques based on cognitive therapy (Higgitt *et al*, 1985; Tyrer *et al*, 1985; Sanchez-Craig *et al*, 1986). However, success depends a great deal on the motivation of the patient, and this is often lacking. The clinician is frequently placed in the position of reviewing the treatment of a patient who does not appear to be helped by benzodiazepines but who cannot seem to cope without them. The patient naturally asks whether any permanent harm can come from continuing benzodiazepines in the long term. This question cannot be answered definitively, but from present evidence there is no unequivocal permanent handicap caused by benzodiazepines in short or long-term dosage. It is worth bearing in mind that the presence of benzodiazepine receptors in the central nervous system implies that there is a naturally occurring substance (an endogenous ligand) that is concerned with the physiological control of anxiety. If this exists, it must be pharmacologically similar to the benzodiazepines, so the notion of benzodiazepines being exogenous poisons is difficult to sustain. However, the existence of endogenous opioid receptors that are binding sites for exogenous opiates shows the dangers of the assumption that what is natural is therefore safe. Currently there are exciting developments that suggest we are close to identifying the exact nature of the endogenous ligand (Stephenson, 1987); if it is discovered, it will have great implications for the development of newer drugs for treating anxiety.

Although benzodiazepines impair memory and other higher aspects of mental function (Lader & Petursson, 1983), this does not always have much impact in discouraging patients from continued use. In the present state of knowledge it is too punitive to withdraw benzodiazepines from long-term users who do not want to stop treatment, and a withdrawal programme forced on an uncooperative patient is an exercise in futility. The usual outcome of this approach in general practice is that the patient leaves the doctor's list and finds another practitioner who is more willing to prescribe benzodiazepines. However, the practice of giving long-term repeat prescriptions of benzodiazepines is not satisfactory. The patient's drug use needs to be regularly monitored, and there should be encouragement to attempt withdrawal whenever the time appears to be propitious.

Which benzodiazepine?

Even if it is accepted that benzodiazepines have a place in psychiatry, there is argument over which preparation is most appropriate for treatment. This task has been made somewhat easier recently by the introduction of the limited list in the United Kingdom. For years it has been realised that there are too many benzodiazepines on the market (Tyrer, 1974; Drugs and Therapeutics Bulletin, 1978). The introduction of the limited list was unsatisfactory in several respects, but there is no evidence that it has been a major loss to treatment. The major difficulty with the benzodiazepines is that some patients have had difficulty in stopping their preferred drug and replacing it by one on the limited list (Drugs and Therapeutics Bulletin, 1987), which suggests dependence on the preferred drug and absence of cross-tolerance when changing to another benzodiazepine.

The most common grouping of benzodiazepines is based on their elimination half-lives, which is roughly correlated with their duration of effect. Anxiety is often markedly episodic (e.g. in phobias) and, even if persistent, varies greatly during the day, and insomnia needs only to be relieved for a maximum of 8 h. It is therefore natural that both pharmaceutical companies and clinicians have tried to develop and promote the use of benzodiazepines with relatively short elimination half-lives up to a maximum of 8 h. Unfortunately, it seems likely that benzodiazepines of short half-life are more prone to cause pharmacological dependence than those with long half-lives (Tyrer *et al*, 1981; Owen & Tyrer, 1983; Kales *et al*, 1983*b*; Griffiths *et al*, 1985).

There are also suggestions that benzodiazepines of higher potency are more prone to dependence than others, but this makes interpretation difficult, as many of the short-acting benzodiazepines are also potent ones, and the average daily dose is less than 5 mg (triazolam, lormetazepam, loprazolam, alprazolam, lorazepam). Unfortunately, there have been insufficient comparative studies to enable the clinician to construct a 'league table' of dependence risks. There are many anecdotal reports (Drugs and Therapeutics Bulletin, 1985) and at least one comparative study (Tyrer *et al*, 1981) suggesting that lorazepam is at particular risk in producing dependence. It is difficult to know whether lorazepam has been singled out unfairly purely because of wide publicity in the media or whether it indeed has a higher potential for dependence. It is a fairly potent benzodiazepine of intermediate half-life (about 14 h) and has been associated with many more reports of dependence than its fellow benzodiazepine of equivalent half-life, oxazepam (Hanna, 1972; Griffiths *et al*, 1984). In the United States, alprazolam, a benzodiazepine of similar potency and half-life, is also getting a reputation for greater risk of dependence than other benzodiazepines. Despite the concern over lorazepam in regular oral dosage, it does have definite advantages in intramuscular dosage over diazepam, as it is absorbed more quickly and excreted more rapidly. It can be of value in treatment of disturbed patients, particularly those with mania (Bick & Hannah, 1986; Jobling & Stein, 1986).

Recommendations

If a psychiatrist feels that drug treatment for an anxious disorder is necessary, benzodiazepines will still figure prominently in the list of options. Wherever possible, their long-term use is to be avoided, because of the risk of pharmacological dependence. They are best used for periods of no more than 2 weeks in regular dosage, or in intermittant flexible dosage. Special care has to be taken when prescribing potent benzodiazepines of short half-life, particularly triazolam and lorazepam, because of growing evidence that they are more likely to lead to the development of dependence.

Review Article

Borderline Personality
A Review of Recent Research

ALEX TARNOPOLSKY and MARK BERELOWITZ

Borderline personality has been, for many years, a discredited diagnostic concept. In 1979 a review of the literature concluded that its validity status was very uncertain. The authors have reviewed research conducted since then and discuss it in terms of the Robins & Guze (1970) criteria. In spite of existing unclear issues, the balance is tipping in favour of the validity of borderline personality, as diagnosed with new research criteria. This development is taking place in the context of a growing interest in the area of personality disorders.

A useful starting point in this discussion of the validity of borderline personality is the review of Liebowitz (1979), which stated that, "When the St Louis approach to diagnostic validity is used as a guideline, the conclusion reached is that available data do not weigh conclusively for or against borderline's status as an independent entity". Since this statement was made, several sets of clinical and research criteria have yielded new data which permit a critical re-evaluation of the diagnosis. These new publications will be reviewed to assess whether the statement that the data "do not weigh for or against" can still be supported. This literature is predominantly American. "Borderline Personality" does not appear in ICD-9 (World Health Organization, 1978), but the term is used by one quarter of the psychiatrists in the UK (Macaskill & Macaskill, 1981; Tarnopolsky & Berelowitz, 1984). Such cases represent about 15–25% of the personality disorder diagnoses in a local ward; they are usually recorded here as suffering from explosive or hysterical personality disorders, or from a depressive illness (Kroll *et al*, 1982). Furthermore, this work illustrates some of the complex issues confronting researchers in personality disorders.

Diagnostic systems

Three well-known diagnostic systems are relevant to this paper: DIB, Spitzer and DSM-III criteria, and Kernberg's psychoanalytic construct.

Gunderson and co-workers (Gunderson & Singer, 1975; Gunderson & Kolb, 1978; Gunderson *et al*, 1981) abstracted symptoms and interactional patterns characteristic of the borderline personality, and developed a semi-structured interview (Diagnostic Interview for Borderlines, DIB) which examines social adaptation, impulse/action patterns, affects, psychotic phenomena, and interpersonal relationships, and which excludes major psychoses. A summary score indicative of borderline personality is derived from 140+ individual questions.

Spitzer *et al* (1979), on the basis of some empirical research, partitioned a hitherto muddled field into two personality disorders: Schizotypal personalities, related to schizophrenia, and Borderline personalities, discussed here. They are chronically unstable, vulnerable individuals, with difficult relationships, poor self-control, and low sense of identity, as described in the DSM-III eight-item checklist (APA, 1980).

Kernberg (1977, 1981) differentiated neurotic, psychotic and borderline "intrapsychic organisations", which are to some extent independent of manifest symptomatology. "Borderline personality organisation" is defined by (a) absence of a stable sense of identity; (b) use of primitive defence mechanisms (splitting and projective identification); and (c) partial retention of reality testing. Kernberg's interviewing method requires both phenomenological and psychodynamic expertise.

The DIB and the DSM-III checklist are essentially phenomenological, and they overlap and also differ. The DIB is wider, including several items on psychotic-like phenomena (brief psychotic episodes, drug-related psychoses, depersonalisation/derealisation) and on social functioning (the adoption of caretaker roles, work performance, and social presentability). However, this is partially counterbalanced by the scoring method: individual DIB items may not influence the final rating if the overall score from that section is too low. The DSM-III checklist contains two items not present in the DIB, namely "identity disturbance" and "affective instability". Kernberg's system is not symptom-based but shares with the DIB the emphasis on certain psychotic features. Furthermore, some of the DIB/DSM-III items are clearly derived from psychoanalysis. For example, "identity disturbance" (DSM-III) originates in Eriksonian ideas; "caretaker roles" (DIB) describes a narcissistic identification.

Reliability and validity

There are so few 'objective' indicators of psychiatric disorder that diagnostic validity is difficult to assess. One could reduce validity to a matter of reliability (i.e. agreement between different assessors about the presence of the disorder), but a more substantial approach consists of marshalling information from a number of areas, and constructing a convincing argument for or against the existence of the disorder (Robins & Guze, 1970). Using this approach we will discuss validity under six headings: identification of a characteristic phenomenology; phenomenological independence from other psychiatric disorders; follow-up data; family studies; laboratory investigations and psychological tests; and treatment response. But first we need to examine the reliability of the diagnostic instruments.

Reliability

Reliability refers to the consistency of an assessment between raters and over time. It is best measured with the coefficient kappa ($\varkappa$), which expresses better than chance agreement ($\varkappa = 0$, chance agreement; $\varkappa = 1$, perfect agreement). In general values above 0.7 are acceptable.

Using the DIB, acceptable $\varkappa$s, in some cases above 0.8, have been demonstrated for live interviews (Kroll *et al*, 1981*a*; Frances *et al*, 1984; Hurt *et al*, 1984), and case notes (McGlashan, 1983*a*; Armelius *et al*, 1985, calculated by us); for the agreement between notes and interviews (Armelius *et al*, 1985); and for two interviews of the same patient by different clinicians at least one week apart (Cornell *et al*, 1983). Individual subscales are also reliable, with only one exception (Frances *et al*, 1984).

For the DSM-III criteria, acceptable $\varkappa$ values above 0.7 were obtained with clinical interviews (Frances *et al*, 1984); perusing case notes (McGlashan 1983*a*); and with a new structured interview ($\varkappa = 0.85$; Stangl *et al*, 1985).

Reliability of Kernberg's method has not been adequately reported (Kernberg *et al*, 1981). Bauer *et al* (1980) showed that blind assessors could differentiate borderline from psychotic "organisation" ($P = 0.024$) using interview transcripts.

In summary, the DIB is the most thoroughly tested and reliable research tool. The promising new DSM-III-based interviews have the advantage of addressing the full range of DSM-III personality disorders. It would be wise to continue using more than one set of criteria as the systems are being reassessed and modified. The reliability of Kernberg's method is not convincing, but the method addresses a different level of pathology, which is not easily measured. Other diagnostic systems which have not gained widespread acceptance include a checklist (Sheehy *et al*, 1980); the Ego Functions Inventory (Perry & Klerman (1980); and two self-report questionnaires (Conte *et al*, 1980; Hyler, in Hurt *et al*, 1984).

Validity: an application of the criteria of Robins and Guze

A unitary clinical description

"In general, the first step is to describe the clinical picture of the disorder" (Robins & Guze, 1970). Does research with the criteria reviewed identify a homogeneous group of patients?

Many studies applied both DIB and DSM-III criteria to case notes (McGlashan, 1983*a*; Pope *et al*, 1983), and interviews (Frances *et al*, 1984; Akiskal *et al*, 1985*a*). Kroll *et al* (1981*b*, 1982) and Barrash *et al* (1983) thoroughly examined 252 consecutive admissions. The DIB identified a larger number of cases than the DSM-III, and there were, naturally, some false positives and false negatives, mostly cases who met the DIB criteria and not the DSM-III. The commonest diagnosis for these discordant cases was non-borderline personality disorder. Cluster analysis improved the agreement and yielded a high sensitivity (0.83) and specificity (0.89) for the DIB against the DSM-III criteria.

In most studies there is a potential source of disparity: the DIB is a research tool, whereas the DSM-III data is obtained in routine clinical interviews. Gunderson *et al* (unpublished) addressed this using a structured DSM-III interview and identified about four-fifths of in-patients with personality disorders as borderline (DIB 84%; DSM-III 74%); sensitivity and specificity were both high, but better for the DIB against the DSM-III than the other way round.

A further improvement requires consideration of the reliability, frequency and discriminative power of each individual item or symptom. Table I shows these with data given by Frances *et al* (1984). When faced with low reliability, it is worth attempting to refine rather than discard the item in question. Kroll

TABLE I

Assessment of certain items diagnostic of borderline personality disorder[1]

Reliability (x)[2]		*Frequency, %*[3]		*Discriminative power (RR)*[4]	
		Gunderson's Diagnostic Interview for Borderlines[5]			
Impulsivity/action pattern	0.79	Social adaptation	86	Impulsivity/action pattern	3.3
Brief psychosis	0.70	Affects	84	Brief psychosis	3.1
Social adaptation	0.69	Interpersonal relationships	68		
Interpersonal relationships	0.67				
		DSM-III Borderline Personality Disorder			
Self-damaging acts	0.69	Impulsivity	89	Emptiness/boredom	4.4
Inappropriate anger	0.68	Affective instability	84	Intolerance/aloneness	3.8
Impulsivity/unpredictability	0.65	Inappropriate anger	80	Impulsivity/unpredictability	3.7
		Interpersonal relationships	77	Interpersonal relationships	3.5
		Emptiness/boredom	75		

1. This table was compiled by us from data published by Frances *et al* (1984).
2. Reliability: items with (*x*) ⩾0.65 are included.
3. Frequency: items present in at least 75% of the cases are listed.
4. Relative risk: calculated by us against non-borderline personality disorders (percentage of cases with item present divided by percentage of controls with item present); values above the median in each set are included; range for DIB was 1.2–3.2, and for DSM–III was 2.4–4.4
5. Each DIB category is a subscale comprising several items; each subscale is scored 0, absent; 1, moderate; 2, severe; only the percentage of score 2 is shown here.

et al (1981*b*) and Gunderson *et al* (unpublished) have examined the diagnostic value of items that appear in only one set.

All this research and work with other criteria (Gunderson, 1977; Sheehy *et al*, 1980; Soloff & Ulrich, 1981) has identified a characteristic borderline diagnostic core of unstable interpersonal relationships, with idealisation and denigration of others, intense unpredictable feelings, and impulsive, often self-destructive behaviour. Similarly, Maudsley psychiatrists think that the most frequent items among the borderlines were a pattern of unstable, intense interpersonal relationships and impulsiveness or unpredictability in potentially self-damaging areas (both DSM–III items); the most discriminating item, however, was brief, stress-related, psychotic episodes or regressions (a Gunderson item) (Tarnopolsky & Berelowitz, 1984). Bateman (unpublished) reported the only diagnostic study of borderline disorders conducted in the UK by a local author. He compared in-patient DIB-diagnosed borderlines with PSE-diagnosed neurotic and psychotic controls. A particularly high level of anxiety and irritability, externalised as violent destructive behaviour, anger, and hostility at interview, distinguished borderlines and neurotics. In addition, they presented depressive and non-specific psychotic features.

Kroll *et al* (1982) highlighted certain differences between British and American patients: "the British borderlines (DIB and DSM–III criteria) reported minimal drug abuse and no drug-related psychosis . . . evidenced no interest in caretaker roles; and although the majority reported derealisation and depersonalisation, so did the majority of British non-borderline patients". These differences should be further investigated.

Reported agreement for Kernberg's method with DIB and DSM–III was over 70% for in-patients, and about 60% for out-patients (Kernberg *et al*, 1981; Koenigsberg *et al*, 1983; Nelson *et al*, 1985). Some flaws limit the conclusions drawn from these studies, and further work using Kernberg's ideas should be undertaken, as his are the only criteria firmly based on a unitary psychological theory.

In summary, although some concordance is expected for sets developed within the same psychiatric culture (and Spitzer consulted with both Gunderson and Kernberg), the agreement found between DSM–III and DIB is high, considering the uncertainty about psychiatric diagnosis generally. However promising, these results say nothing about which instrument is more valid, a question to be resolved only by observing the relationship of external factors, such as prognosis, family distribution and treatment response, with the diagnostic criteria. In turn, the analyses ought to be extended to individual items in each set, a type of study only just being published (Goldberg *et al*, 1986; Soloff *et al*, 1986). So far we conclude that there is enough agreement in terms of reliability and clinical description to justify proceeding to another step of inquiry.

Phenomenological discrimination from other disorders

The question here is whether patients with an operationally diagnosed borderline personality can be distinguished from patients with other psychiatric conditions, in particular with schizophrenia, affective disorders, and other personality disorders.

Schizophrenia. Several studies with different methods have now placed the phenomenological distinction between borderline personalities and schizophrenic in-patients beyond reasonable doubt (Gunderson *et al*, 1975; Kolb & Gunderson, 1980; Soloff & Ulrich, 1981; Kroll *et al*, 1981*b*, 1982; Pope *et al*, 1983). For example, Gunderson *et al* (1975), using patients taken from the International Pilot Study of Schizophrenia, found that the borderline in-patients had significantly fewer psychotic symptoms than the schizophrenic group, with no evidence of thought disorder. The borderline group was also characterised by derealisation, a frenetic and stormy life-style, unusual and occult experiences, marked interpersonal difficulties, and suicide threats. Kroll *et al* (1981*b*) found only one DSM-III schizophrenic among 21 DIB-positive in-patients, and Pope *et al* (1983) found no DSM-III schizophrenics among 33 in-patients diagnosed as borderline according to Gunderson criteria.

However, the distinction between out-patients is less clear and less studied. Sheehy *et al* (1980), comparing borderlines (own criteria) and schizophrenics (Carpenter criteria), found that deficient management of impulses, intolerably unpleasant feelings, and idealisation/denigration of others were significantly more prevalent among the borderline patients. Pronounced failure of reality testing was more frequent among the schizophrenics, and was the best predictor of group differences. But Koenigsberg *et al* (1983) found that borderline out-patients had only non-significantly higher DIB scores than schizophrenic out-patients. These results are conflicting and also questionable. Sheehy's borderline criteria were not applied with research rigour, and Koenigsberg reported only global DIB scores for borderline patients versus a small heterogeneous control group of schizophrenic and manic-depressive patients. Therefore, while the distinction between florid forms of schizophrenia and borderline personality is well established, the distinction between milder forms of the two disorders requires further research.

Affective disorders. The coincidence of affective illness with borderline personality is much greater than statistically expected (Gunderson & Elliott, 1985; Perry, 1985). This relationship is also more complicated than the previously postulated inclusion of borderline personality under schizophrenia, and Gunderson & Elliott (1985) have listed four hypotheses to explain it. Two are that one disorder can be reduced to the other; for example, (a) drug-taking or promiscuity to relieve feelings of emptiness, dysphoria or depression, or (b) depression resulting from impulsivity and unsatisfactory relationships; the third (c) is that both disorders coexist independently in the same subjects; and the fourth (d) – their own, in the Meyerian tradition – postulates that affective symptoms or character traits arise from an interaction of influences peculiar to each individual. Research partially supports all the hypotheses, although Gunderson & Elliott's analyses lead them to accept the fourth.

In this section, evidence about the phenomenological distinction between borderline personality and a variety of affective disorders is considered. Gunderson & Kolb (1978) were able to discriminate borderline personality from neurotically depressed in-patients by the presence of drug-related psychotic experiences, anhedonia and dysphoria, interpersonal difficulties, and paranoid experiences. Sheehy *et al* (1980), with less formal methods, obtained similar results in a series of out-patients. Barrash *et al* (1983), summarising the findings of Kroll's group on 252 in-patients, found 48 with DIB-positive borderline personality and 77 patients with "affective disorders" not further specified; only three patients with affective disorder were DIB-positive. Soloff & Ulrich (1981) found that total scores, scaled section scores, and 19 individual DIB items all effectively differentiated borderline personality from RDC major (unipolar) depressives. It was also repeatedly noted that the items characteristic of each disorder are different (e.g. impulsivity *v.* affective state); and that the attendant emotions are different, the borderline personalities' 'depression' having schizoid qualities of boredom and emptiness. Borderline personalities also feel easily disappointed and let down, want to hurt themselves and are well aware of their rage.

By contrast, other studies of in-patients (Pope *et al*, 1983) and out-patients (Akiskal *et al*, 1985*a*) have found a proportion as high as 50% of major and minor affective illnesses among DIB-positive patients. It is of local interest that the British sample ($n = 47$) studied by Kroll *et al* (1982) showed seven DIB-positive cases, three with a secondary diagnosis of depressive neurosis and one with a primary diagnosis of major affective illness (DSM-III). Also, Bateman's (unpublished) pilot study in London found that among eleven in-patient DIB-borderlines, ten met the

PSE criteria for minor, and one for major, depressive disorders, although they differed in other ways (see above).

Independently of the procedural differences between the papers, our view is that this issue cannot be fully solved with single cross-sectional descriptive studies where the distinction between long-term personality traits and episodic affective symptoms is obscured; nor in a single centre, because of sample variations influencing the intake of patients to individual institutions. We will take up this discussion below with data from follow-up, family, and therapeutic studies.

Personality disorders. Several studies have failed to discriminate between *in-patients* with DIB borderline and non-borderline personality disorders (Kolb & Gunderson, 1980; Kroll *et al*, 1981*b*, 1982); Pope *et al* (1983) found that DSM-III borderline overlapped with histrionic personality disorder in women, and with antisocial in men. However, severity may be relevant, because cases could be distinguished in at least three *out-patient* samples (Sheehy *et al*, 1980; Perry & Klerman, 1980; Koenisgberg *et al*, 1983). More importantly, Barrash *et al* (1983) reanalysed with cluster analysis Kroll's in-patient samples and were able to distinguish between borderline and other personality disorders.

It should also be objected that (a) the diagnoses of non-borderline personalities were not standardised; and (b) assessing one single personality disorder ignores their multidimensional presentation. Both objections were met by Stangl *et al* (1985), who found, among out-patients, overall agreement ($\varkappa > 0.7$) for the presence of any personality disorder, and for the presence of three individual types, borderline, histrionic, and dependent. The most frequent combination was borderline and histrionic, a finding related to that reported by Pope *et al* (1983), predicted by the DSM-III subgroup of 'dramatic' personality disorders, and obtained with cluster analysis by Kass *et al* (1985). The data of Frances *et al* (1984) further support the multidimensional viewpoint: in a sample of 26 borderline and 50 non-borderline out-patients, two-thirds of each group met the criteria for at least two DSM-III personality disorders.

So far this research shows, firstly, that some individual personality disorders (borderline or other) may be distinguished from each other, and secondly, that they may coexist in a variable number of subjects. This is also borne out by borderline and schizotypal personalities: (a) a large percentage of cases meet the criteria for both disorders (Spitzer *et al*, 1979; Frances *et al*, 1984), but (b) the two clusters can be separated by statistical analysis (Spitzer *et al*, 1979; Gunderson *et al*, 1983; Barrash *et al*, 1983). Furthermore, (c), no schizotypal patients were found in other borderline personality disorder samples (Pope *et al*, 1983); or the overlap was small (Kroll *et al*, 1981*b*, 1982; Akiskal, 1985*a*; Gunderson *et al*, unpublished). George & Soloff (1986) identified the risk of over-reliance on a single symptom group to distinguish the two. More about this is given in the next two sections.

Follow-up

Follow-up studies establish whether the patients can be said over time to have some other disorders which can better explain their original symptoms (Robins & Guze, 1970). A central question was whether borderline personalities were in fact not suffering from an early form of schizophrenia. In a five-year follow-up before the DIB and DSM-III were introduced (Carpenter & Gunderson, 1977), all the schizophrenic patients retained their original diagnoses but there was persistent diagnostic uncertainty about the borderline group. Despite the uncertainty, however, only one of the 24 borderlines was subsequently diagnosed as schizophrenic. More recently, no schizophrenics were found among DIB or DSM-III borderline samples after 4–7 years (Pope *et al*, 1983, $n = 27$) and after three years (Barrash *et al*, 1985, $n = 30$).

The second question concerned the relationship between borderline personality and affective illness. Pope *et al* (1983) found that of the mixed (borderline and affective) cases, 74% had possible/probable affective illness at follow-up, while the corresponding figure for the 'pure' borderline was only 23%. Akiskal (1985*a*) found a similar figure, 20% for melancholic episodes among 'pure' borderlines. Moreover, major depressions were equally prevalent among borderline and other personality disorders at three years, which argues against a *specific* link between borderline and affective disorders (Barrash *et al*, 1985).

The third question concerned the stability of borderline personality over time. The majority retained their original diagnosis (65% Pope, 60–90% Barrash), but some, in addition, received other personality disorder diagnoses as well, mainly in the 'dramatic group' (Pope). In only one or two cases was the diagnosis of schizotypal personality considered possible or present. McGlashan's (1983*b*) informal follow-up (average 15 years) on a large sample showed not only that few (16–24%) borderline personalities changed into schizophrenics, but also that 55% schizotypals developed schizophrenia.

The last question concerned social functioning. The presence of similar social outcome is a weaker argument for validity than the persistence of the diagnosis, for there is no one-to-one relationship between psychopathology and social functioning. Nonetheless, after five years, borderline patients had significantly better social functioning than schizophrenics (Carpenter & Gunderson, 1977), although at two years there had been no difference (Gunderson *et al*, 1975). In later studies, 'pure' borderline personalities presented outcomes intermediate between those of schizophrenic illness (worst) and affective illness (best) (Pope *et al*, 1983; McGlashan, 1983*b*, 1986).

In summary, borderline personalities tend to retain their diagnoses over time, but in addition they may present with other personality disorders, frequently of the 'dramatic' type. Several studies show that only a minority develop schizophrenia, in contrast with schizotypals. The majority of borderline personalities do not develop affective illness; a variable number display affective symptoms at follow-up, but probably no more than for other personality disorders. And the other way round? No one has yet examined whether affective illness resolves into a borderline state (Gunderson & Elliott, 1985). The hypothesis that borderline personalities are a variety of major affective illnesses is weakened by follow-up studies. Anecdotal evidence also indicates that symptoms tend to dilute with increasing age (confirmed by McGlashan, 1986), and that a tolerant partner, who buffers the patient's tendency to overreact, also helps. These issues too demand further attention. The natural history of the borderline disorders is only partially written; more work contributing to the debate about validity and providing a baseline for therapeutic trials is necessary.

Family studies

Robins & Guze (1970) argue that finding an increased prevalence of the same disorder in the relatives and in the index patients supports the validity of that diagnosis. Twin studies help to disentangle the relative aetiological importance of heredity and environment.

In this section we must consider both borderline (DSM–III or DIB criteria) and schizotypal personalities (the current concept of "borderline schizophrenia" in DSM–III), and their relationship to schizophrenia. In the Danish Adoption Study, Kety *et al* (1968) identified "B–3 or borderline schizophrenics" among index cases and relatives. The B–3 relatives were in the main relatives of schizophrenic index cases, supporting a genetic link between the two. A sample of B–3 subjects was used by Spitzer to define the criteria for DSM–III Schizotypal Personality Disorder. Kendler *et al* (1981) blindly applied Spitzer's criteria to the Danish records and confirmed that the schizotypals were more frequent among the biological relatives of chronic schizophrenic patients than among either relatives of controls or relatives of index B–3 cases. Gunderson *et al* (1983) went further, blindly reexamining the same records to look at both schizotypals and borderlines. They confirmed that among the B–3 relatives of chronic schizophrenics, the most prevalent diagnosis was schizotypal personality, not borderline. They also showed that the commonest diagnosis in the B–3 *index* cases was borderline personality (9 out of 10), and that their B–3 relatives had borderline rather than schizotypal features. These two studies therefore allow for two genetic propositions: (a) the mentally ill biological relatives of chronic schizophrenics are schizotypal and not borderline, and (b) the mentally ill relatives of borderline personalities are, in the main, themselves borderline. These propositions were supported by other samples; for example, among students and university staff (Baron *et al*, 1985). Also, Loranger *et al* (1982) found that borderline personality was ten times more common in the treated relatives of borderline patients than in the relatives of schizophrenic patients. Monozygotic twins of schizotypal patients have schizotypal disorders (33%) and not borderline (0%) (Torgersen, 1984). The most frequent diagnoses among relatives of borderline patients were 'dramatic' personality disorders (Pope *et al*, 1983).

The situation is complicated by the alternative hypothesis that borderline personality is genetically linked to affective illness (Stone, 1977). Among others, Soloff & Millward (1983) are often quoted to support this hypothesis, as they found that more borderline than depressed probands had relatives with "mood swings". This result, however, refers to a mixed group of 19 borderlines, 9 schizotypals and 20 cases who met both criteria; further analyses revealed the "depression" was actually more prevalent among relatives of schizotypals than borderlines. The homogeneity of the sample seems to be a crucial methodological precaution. Pope *et al* (1983) and Andrulonis & Vogel (1984) simply separated 'pure' borderlines from those who also had an affective illness, and found that the prevalence of depression was raised only in the relatives of the second, mixed, group. Torgersen (1984) found the same: "all the co-twins with an affective disorder were co-twins of schizotypal and borderline patients with a concurrent affective disorder as well". On the other hand, numerous objections can be raised against these studies. The re-examinations of the Danish Adoption records are a secondary retrospective analysis, vulnerable to circularity – this was the sample from which the schizotypal set was originally defined. Torgersen's was the only twin study, and he was not blind to who was twin to whom. The identification and/or diagnosis of cases and relatives is open to question in many of the studies, and can be criticised in some of them.

In summary, we are left with consistent evidence, albeit of diverse quality, leading to an attractive hypothesis: that 'borderline' and 'schizotypal' are dimensions that coincide in some subjects, but nevertheless have separate pedigrees. What is needed to further test this is a multi-centre twin study (to ensure adequate numbers and avoid idiosyncratic samples), with careful attention paid to the distinction between pure and mixed cases, and to the identification and assessment of the relatives at risk, not just the probands.

Laboratory investigations and psychological tests

Biological data is as sparse and inconclusive in the area of borderline personalities as it was for the whole of psychiatry 15 years ago (Robins & Guze, 1970).

Much of the work with biological markers to assess the relationship with affective disorders is questionable, either because the cases studied had both syndromes concurrently (Carroll *et al*, 1981), or because watertight controls were not available. Akiskal *et al* (1985*b*) described a REM sleep pattern in borderlines similar to that found in depressives; there were differences, however, between those borderlines who had had an affective diagnosis at any time in the past and those who had not. Coid *et al* (1984) found a raised level of plasma metencephalin among self-mutilators who met DSM-III borderline criteria.

Singer (1977) has reviewed the literature on psychological tests. In brief, borderline personalities show ordinary reasoning on highly structured tests, but on projective ones they "demonstrate flamboyantly deviant reasoning and thought processes". Test results distinguish between borderline and schizophrenic in-patients, but for out-patients the distinction is less clear. Borderline patients' responses to WAIS, Rorschach and other tests have been reported (Kernberg *et al*, 1981; Soloff & Ulrich, 1981). Borderline personalities in both the USA and the UK showed a characteristic Minnesota Multidimensional Personality Inventory (MMPI) profile: 8 = schizophrenia, 4 = psychopathic deviate, and 2 = depression (Kroll *et al*, 1981*b*, 1982). MMPI scores also differentiate borderline from schizotypal personality (Goldberg, 1985; Stangl *et al*, 1985).

In one study, family features were blindly rated: Gunderson *et al* (1980) found that over-involvement between the parents, with neglect of the offspring, distinguished borderline from schizophrenic and neurotic families.

In summary, it is premature to draw conclusions from the biological data, but the results of psychological tests are in keeping with clinical observations (e.g. regression in unstructured situations) and with other research (e.g. difficulty in differentiating borderline from schizophrenic out-patients). The observation of a particular family pattern should be replicated with wider samples and other methods.

Treatment response

Although not specifically mentioned by Robins & Guze, treatment response contributes to the delineation of a disorder: therapeutic success may suggest the existence of a specific pathogenic or aetiological factor (e.g. Teitelman *et al*, 1979). Few controlled studies of treatment exist: this is probably because of the lack, until recently, of reliable diagnostic criteria; because psychoanalytic psychotherapy is only described in case reports; and because of the nihilism of many psychiatrists about personality disorders. Early pharmacotherapy studies illustrate, more than anything else, the conviction of the writers as to which of the major psychoses borderlines should be affiliated, and/or existing differences in their patients' presentation.

Antidepressants (Klein, 1977) and low dose neuroleptics were used (Brinkley *et al*, 1979; Serban & Siegal, 1984). Recently two double-blind, placebo-controlled trials reported the efficacy of moderate dose of neuroleptics on chronic severe populations. On one sample of volunteers, the effect on psychotic-like symptoms was noted (Goldberg *et al*, 1986); on another, of in-patients, the effect on psychotic-like and affective symptoms was noted (Soloff *et al*, 1986). The latter also tried amitriptyline and patients got worse, a point raised by Gunderson (1986) to argue the independence of borderline personalities from affective disorders (cf. also Gardner & Cowdry, 1985). These important papers improved the therapeutic trials to acceptable current standards; but Goldberg *et al* too hastily suggest that the diagnostic criteria be changed to fit the target of a particular drug. The approach advocated in this review is wider.

The classic Menninger Clinic project (Kernberg *et al*, 1972) compared supportive psychotherapy, classical psychoanalysis and "expressive psychotherapy" conducted in an in-patient unit, to the third of which borderlines responded best. The sophistication of this study make the thought of replication daunting, but it is nevertheless surprising that nobody has attempted it.

In summary, good studies are just becoming available and have not yet contributed substantially to the issue of validity. Double-blind trials of medication, with detailed analyses of the effects, should continue and also be expanded to include psychotherapy with a design that helps identify the relative benefit of each (cf. Di Mascio *et al*, 1979).

Discussion

The papers reviewed, over 70 in all, published mainly between 1980 and 1986, show progress towards demonstrating the validity of borderline personality in terms of verifiable criteria. Three contributions were influential in this development.

In conceptual terms, Spitzer *et al* (1979) distinguished borderline ("unstable") from schizotypal ("borderline schizophrenia") personalities, a distinction empirically supported by themselves and others. The most important input to the research field, however, was Gunderson's Diagnostic Interview for Borderlines. The DIB conceives of borderlines in categorical terms, but this simplification has proved fruitful. The DIB provides a diagnostic score, like a screening instrument. More work is necessary on the relationships between the 140+ individual items; on the existence of subgroups (as a positive score can be obtained with different combinations of diagnostic statements); and on the prediction of external indicators. The third contribution, Kernberg's psychodynamic theory, is potentially amenable to ordinary research but little has been published so far. A fair assessment of Kernberg's psychoanalytic thinking has not been attempted here.

Research reviewed show that a group of patients with similar traits and symptoms sustained over a number of years can be identified in many institutions, in different countries, and in the community (Drake & Vaillant, 1985). It is frequently asked if borderlines are not a product of the North American culture. Borderline pathology has been recognised for years by psychoanalysts of different continents, and more recently by researchers in Europe (Kroll, Dahl, Torgersen, Bateman, Coid), in Australia (Mellsop) and among Hispanic samples in the USA (Castaneda & Franco, 1985). These patients are "unstable", "unpredictable" or "inconsistent" in their affects, impulses, identify and relationships, and are prone to transient psychotic episodes. Several research diagnostic criteria exist and they partially overlap, as is the case for other well-established psychiatric diagnoses: schizophrenia, for example, where they are also only partially concordant (Brockington *et al*, 1978). It will not surprise anybody if research shows that different sets, dimensions, or items of the borderline concept have different predictive power in terms of other variables; for example, prognosis (as shown for schizophrenia sets by Brockington *et al* (1978)), or heritability (as shown for schizophrenia by McGuffin *et al* (1984)).

Borderline personality and schizophrenia

To sustain its validity, the borderline concept had to prove first its separateness from schizophrenia. Independent studies with various criteria give the common message that borderline personalities and in-patient schizophrenics are reliably distinguished. Their longstanding features of borderline personalities stand out (e.g. impulsivity, chaotic lives, stormy relationships) and are remarkably different from those of the schizophrenics. In spite of some similarities (e.g. depersonalisation or derealisation) their symptoms also differ (e.g. characteristic phenomenology and course of the psychotic phenomena, cf. Pope *et al* (1985)). Furthermore, outcome, treatment response, psychological testing, and family studies all indicate that borderline personality as currently diagnosed is not a variety of schizophrenia. However, in out-patient settings, the distinction with milder, torpid, or remitted schizophrenics has not been studied well and is not so clear. We will suggest why, below.

Borderline personality and affective disorder

A variable, sometimes high proportion of cases present with both affective and borderline symptoms, at intake and follow-up. Firstly, depressions are common and multifarious conditions, the presence of which do not necessarily suggest that the concomitant personality disorder is dependent on them. Clinically, the assumption made is different: that some personalities are predisposed to depression. Secondly, the most characteristic features are not identical; the quality of the depression is frequently different. Barrash *et al* (1985) have shown that *other* personality disorders are equally at risk for depression, arguing against a specific unity between borderline and affective disorders.

Cases where both symptoms co-exist may explain some ambiguities: the development of affective symptoms such as dysphoric mood or self-harm cause borderline personalities to be admitted to hospital, when they appear more like affectively ill patients; among out-patients, while not in crisis, the more schizoid features such as aloofness and doubts about themselves may predominate, obscuring the distinction from remitted schizophenics (a hypothesis to test).

Thirdly, an excess of cases with depression has been found at follow-up, but these were considerably reduced when affective disorders were controlled for at the initial interview. It follows that 'pure' and 'mixed' cases should be independently analysed in future studies. The same applies to family studies: an excess of affective disorders was found among the relatives of the mixed (borderline plus affective) cases, not among the relatives of 'pure' borderlines. It also seems – procedural weaknesses considered – that the most frequent diagnosis among the latter is borderline personality itself.

Fourthly, the precise variety of affective disorder should be specified, as different hypotheses about the unity apply. Biological markers would contribute valuably to this debate. Similarly, Kernberg argues that some but not all depressives function at borderline level; and depression is less likely in personalities with both borderline and antisocial features, which is consistent with the psychodynamic link of aggression and depression (Perry, 1985).

At one point it was somewhat dramatically thought that if borderlines could not be reduced to a schizophrenic-like condition they would be subsumed *in toto* under affective disorders, removing any basis for their validity. On present evidence this is not likely, but it might be either that some borderlines are particularly prone to depression, or that one subgroup is truly a sub-affective disorder. Depressive features were common in two studies in the UK, where the issue could be profitably examined. But if the different proportions of cases with depressive symptoms reflect uncontrolled selection of patients at intake, an epidemiological survey – or at least a multi-centre study – will be required.

Borderline and other personality disorders

The distinction between borderline and other pathological personalities must be discussed in terms of categories and dimensions. Following Frances (1982), these are not mutually exclusive concepts. Categories are extreme, paradigmatic or severe forms of a continuum, cases where a particular sector of the personality pathology is so extreme that by comparison others are overshadowed. Adopting a categorical model is expedient and simplifies research – witness the DIB. Somewhere in the process, however, the researcher is faced with a triple variation: (a) cases that differ in severity, (b) cases that only partially satisfy the criteria, and (c) cases where the category appears accompanied by others – now it may be called a dimension. The researcher is required to change from an ordinary to a wide-angle lens. A multidimensional approach is more true to clinical practice, and more realistic – although more complex to handle – for therapeutic trials.

The papers reviewed support the validity of borderline personality and the standing of a multidimensional approach. Succinctly: (a) the individual diagnostic items can be reliably assessed (e.g. Frances *et al*, 1984); (b) they cluster in stable sets, confirmed statistically (e.g. Spitzer *et al*, 1979; Barrash *et al*, 1983); (c) varieties exist, defined by the severity or completeness of the sets (e.g. Koenigsberg *et al*, 1983; Kass *et al*, 1985); (d) they appear both in pure forms and in combination (e.g. Pope *et al*, 1983; Frances *et al*, 1984; Stangl *et al*, 1985); and (e) some combinations are more frequent (e.g. borderline plus histrionic or schizotypal). However, these studies have not examined the whole spectrum of personality disorders, only the specific varieties noted above. The true distribution of pure/mixed forms would only come from epidemiological surveys. The need to study the existence of varieties within the current concept of borderlines is confirmed by many studies. The search for a unitary description of the borderline personality has led to the relative neglect of its possible heterogeneity. However, the existence of subtypes has always been argued for by descriptive (Grinker *et al*, 1968; Andrulonis & Vogel, 1984), pharmacological (Klein, 1977), and psychoanalytic (Rosenfeld, 1979) findings. The DIB captures a pathognomonic pole of impulsivity and unpredictability with proneness to psychotic episodes. Another pole, of identity pathology, as yet less reliably assessed, and less studied, should be explored further (it is relevant for the assessment of psychotherapies based on object-relations theory.) It is also possible that varieties will become more firmly established on aetiological grounds (e.g. brain damage (Andrulonis & Vogel, 1984)), by the proximity to affective disorders or by response to treatment.

Researchers should identify their cases with more than one set of criteria and assess for other personality disorders as well, to contribute to the debate about validity and about multidimensionality. It is foreseeable that new work will modify the diagnoses now employed and progressively change current theoretical and pragmatic assumptions about personality disorders.

Conclusion

We can now modify Leibowitz's statement to say that the scale has tipped in favour of the diagnostic status of borderline personality. What before was a vague, mythical or muddled concept has achieved in many ways the significance of other commonly used psychiatric diagnoses. By this we mean that it has become a reasonable working description, assessed with acceptable objective criteria, allowing systematic investigation of its contents and of its limits, and useful to guide some clinical decisions. However, we would caution against the complacent reification of the diagnosis, as research in new – and some old – issues is clearly needed. These developments have taken place in the context of a growing interest in the whole field of personality disorders. If the 1970s were years of a renewed interest in schizophrenia, and the 1980s are witnessing considerable research in affective disorders, the 1990s will show unexpected developments in the investigation of personality disorders.

'The Schizophrenias as Nervous Types' Revisited

GORDON CLARIDGE

In 1972 the author proposed that schizophrenia represents an aberration of central nervous processes that underlie cognitive and personality characteristics which can be observed in many healthy people. The present paper brings the evidence for that theory up to date and concludes that over the past 15 years it has received considerable empirical support. The way in which the theory confronts the question of whether or not schizophrenia is a disease is also clarified.

Some 15 years ago (Claridge, 1972), a perspective was offered on schizophrenia – or, more strictly, the schizophrenias – based on the idea that they "represent, in an exaggerated form, cognitive and personality characteristics found distributed in the general population." This conclusion was arrived at on the basis of evidence from genetic and other studies of schizophrenia, data from the author's own research, and theoretical concepts drawn from experimental and personality psychology which supported that 'dimensional' view of the psychotic states. Since then, a great deal of additional data has accumulated in these fields of research, and some of the theoretical issues have been further clarified. There have also been changes of viewpoint elsewhere about schizophrenia, with decline of the antipsychiatry movement and, as a backlash, the strong return in conventional psychiatry to organic disease explanations. It therefore seems timely to return to the ideas presented in the 1972 paper and see how they now stand, when judged against other contemporary opinions about schizophrenia.

The schizophrenias as nervous types – 1972

A first, and very important, feature of the 1972 model was its essentially *biological* nature, when compared with other theories (e.g. those of the antipsychiatrists), which, although also arguing for a continuity between psychosis and health, did so on entirely different grounds. A second, and related, point concerns the meaning of the concept of 'nervous types' around which the model was constructed.

The term 'nervous type' was first used by Pavlov (1928) to explain the fact that animals employed in his conditioned reflex experiments varied widely in their behaviour. He proposed that individual nervous systems differ in certain important physiological properties which can be observed overtly as variations in canine temperament. Since then, the idea has been elaborated and applied to human personality by several East European psychologists (Teplov, 1964; Nebylitsyn, 1971; Strelau, 1985). It has also formed the cornerstone of theory for most psychologists in the West who have sought a biological explanation of human individual differences. Notable here is Eysenck (1967), whose writings, more explicitly than most, also articulate another feature; namely the assumed continuity between those biological characteristics that underlie *normal* individual differences in behaviour and those responsible for *abnormal* or aberrant functioning: according to Eysenck (and others who take a similar viewpoint), particular varieties of 'nervous type' can take extreme forms, and it is they who represent the psychiatrically disordered.

Attempts to apply 'nervous type' theory to psychiatric illness are least controversial in the case of the neuroses and other mild forms of disorder. Thus, few would seriously challenge the suggestion that in anxiety neurosis the symptoms partly derive from the patient's more fearful temperament and hence more physiologically reactive nervous system (Gray, 1982); or that some kinds of antisocial behaviour are motivated by chronic 'sensation seeking' of biological origin (Zuckerman, 1979); or that each of these qualities can be found to a lesser degree in many psychologically normal individuals.

Not so well accepted is the possibility that the same may apply to the psychoses, including schizophrenia – that there may be many perfectly healthy people who have (to borrow a term from later in this paper) a 'schizotypal' nervous system, which stands in the same relationship to schizophrenia as, say, the anxious person's nervous system does to anxiety neurosis. Yet even in 1972, the idea was by no means new. For example, the antecedents of the continuity viewpoint could be seen in Kretschmer's (1925) notion of 'schizothymia–cyclothymia' as a dimension of normal temperament; and there already existed plausible polygenic models of inheritance to

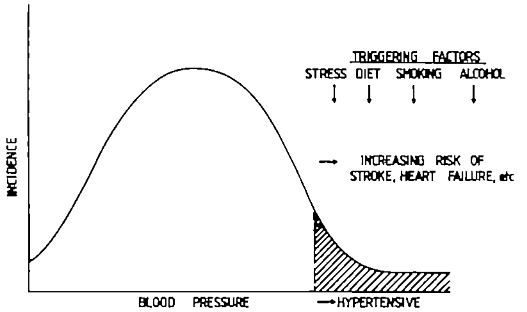

FIG. 1 The continuum of blood pressure as disposition to hypertension-related disease.

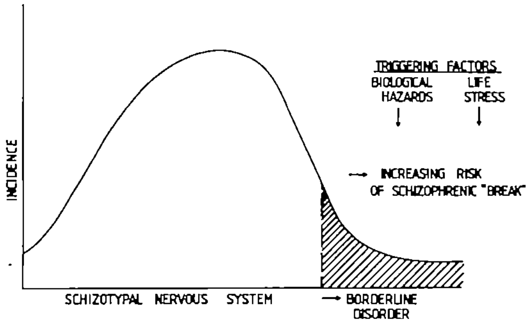

FIG. 2 The hypothetical continuum of 'schizotypy' as predisposition to schizophrenic disorder.

account for the graded manifestation of psychotic characteristics (Gottesman & Shields, 1968).

What was lacking in 1972, however, was a systematic body of information on two points: (a) how to measure schizophrenic-like traits in normal people, and (b) whether such traits have correlates elsewhere in behaviour and in the central nervous system. The thesis developed then was largely based on existing, rather scattered, evidence and on extrapolations from data collected in the course of psychophysiological investigations of clinical populations.

Another ambiguity in the earlier paper was its failure to deal with a crucial issue – how to reconcile a dimensional view of the psychoses with their undoubted status as diseases. Thus, the original model made no clear distinction between 'nervous type' as a descriptor of the enduring biological and personality characteristics of an individual, and its use to describe the same person when psychiatrically disturbed. Put another way, it did not distinguish those trait-like qualities of biological variations that have to do with the *predisposition* to illness and those which come into play during illness itself, giving rise to symptoms.

Predisposition and Illness

One frequently encountered hurdle to acceptance of these ideas is the conceptual difficulty of reconciling a view of schizophrenia as disease with the proposition that the latter has a certain continuity with psychological health. That the two are not as incompatible as they might seem becomes evident, however, if we consider what *kind* of disease schizophrenia could be. The suggestion to be made here has in fact been developed fully elsewhere as a *general* model for psychiatric disorder (Claridge, 1985), although this paper is concerned only with how it can be applied to schizophrenia.

The argument rests on a parallel that can be drawn between schizophrenia and the systemic physical disorders, the example to be used here being the hypertension-related diseases (Fig. 1). A necessary condition for such diseases to occur is sustained raised blood pressure. Yet blood pressure itself, as a naturally occurring characteristic, is merely a sign of a functioning organism and, like many other such traits, varies quantitatively in the population. On the other hand, it can also act as vehicle for disease, under certain pathogenic conditions and in some individuals with particularly high levels. In this example, therefore, blood pressure can be said to have *dual* properties: as a normal adaptive trait and as a potential predisposition to disease. The diseases (e.g. stroke) which it helps to mediate when acting as disposition can be distinguished by virtue of the new and increasingly catastrophic discontinuities of function that they bring about. In the case of the physical systemic diseases, therefore, there is no difficulty – and no controversy – about reconciling the presence of features in aetiology that are dimensional and those that involve a break in normal functioning.

A similar perspective can usefully be taken on schizophrenia (Fig. 2). The schizophrenic 'break' can indeed be seen as a discontinuity in behaviour – and therefore in brain function, thus preserving intact the notion of schizophrenia as a disease. However, this is perfectly compatible with the underlying disposition being dimensional, and describable as biological and psychological traits which, in the absence of triggering factors and when occurring in moderate degree, merely represent ways in which healthy human nervous systems vary.

In the 1972 paper the so-called 'borderline states' were quoted as evidence, in the clinical domain, of continuity in schizophrenia. Since then such conditions have received increasing attention, particularly in American psychiatry (Stone, 1980;

TABLE I
Psychotic trait scales

Scale	*Reference*	*Comment*
Schizotypy	Golden & Meehl (1979)	Based on MMPI items
Chapman scales		
Perceptual aberration	Chapman *et al* (1978)	Also scales of Nonconformity and Hypomania
Magical ideation	Eckblad & Chapman (1983)	
Social & physical anhedonia	Chapman *et al* (1976)	
STQ Schizotypal personality (STA) Borderline personality (STB)	Claridge & Broks (1984)	Modelled on DSM-II criteria for 'schizotypal personality disorder' and 'borderline personality disorder'
Predisposition to hallucination	Launay & Slade (1981) Bentall & Slade (1985 *b*)	Perceptual item content
Schizophrenism	Nielsen & Petersen (1976)	Attention/thought process items
Schizoid cognitions	Rust (1987)	Derived from multi-scale inventory of psychotic cognition
Psychoticism (P-scale)	Eysenck & Eysenck (1975)	Part of Eysenck Personality Questionnaire (EPQ)

Schizophrenia Bulletin, 1979, 1985). Although precise definition still remains a problem, the clinical form of the borderline disorders and the probable genetic relatedness of the schizotypal variety to schizophrenia (Kety, 1985) suggest that they do indeed represent muted forms of full-blown psychosis. As such, they provide another instance of the parallel drawn here between schizophrenia and the physical systemic diseases, where the existence of mild or subclinical varieties of disorder is well recognised.

In summary, as Gottesman & Shields reaffirmed in their 1982 book, schizophrenia can readily be seen as a diathesis-stress disorder, the underlying genetically determined disposition to which has a varying quality. How the latter manifests itself as phenotypic variation in the general population is a serious question for research on the aetiology of schizophrenia, and is one which the studies reviewed in the remainder of this paper were designed to answer.

An update of evidence

The bulk of the work to which we shall refer here has attempted to measure in normal subjects – usually adults – characteristics which can also be found in schizophenic patients. This research has generally proceeded through two phases: one, descriptive, in which personality and cognitive traits thought to be relevant are identified and measured by questionnaire; and a second in which high-scoring individuals on such questionnaires are examined with respect to some objective characteristic drawn from the schizophrenia literature or chosen on theoretical grounds as potentially significant in understanding the schizophrenic process.

Another strategy, which converges on the questionnaire method, is that used in 'high-risk' research. There the subjects are chosen according to their genetic affinity to a known schizophrenic, on the grounds that such individuals are more likely to show the traits that describe the disposition to schizophrenia. This method can merely entail studying the adult relatives of schizophrenics, but is found in its most complete form in the longitudinal follow-through studies of children considered to be at high risk for schizophrenic breakdown. A complete review of high-risk research is beyond the scope of this paper; but a recent volume has brought together details of most of the projects either completed or currently in progress throughout the world (Watt *et al*, 1984). Reference will be made to these investigations where the results can be brought to bear on the findings from questionnaire studies.

Questionnaire measurement of psychotic traits

Since the 1972 paper was published there has been a steady stream of questionnaires purporting to measure psychotic traits in normal adults: the more prominent of these are listed in Table I. Although most are recent, the thinking behind several of them goes back much further than 1972. In particular, the term 'schizotypy' was first coined in 1962 by Meehl to denote a form of schizoid personality detectable from a subset of Minnesota Multidimensional Personality Inventory (MMPI) items, validated against the full MMPI profile of schizophrenics and pre-schizophrenics (Golden & Meehl, 1979).

The remaining scales shown in Table I have had various labels attached to them and have differed considerably in comprehensiveness, item content, and theoretical standpoint from which they were devised. The most complete set is that constructed by Chapman and his colleagues, who have concentrated on measuring separately distinguishable features of schizotypy, such as anhedonia and perceptual aberration, items being drawn from clinical signs of schizophrenia. The validity of these scales, when used in normal subjects, has been successfully tested against clinical data obtained from the Schedule for Affective Disorders and Schizophrenia, Lifetime version (SADS-L) interview procedure (Chapman & Chapman, 1980; Chapman *et al*, 1980).

Other, more recently developed, instruments are Rust's Inventory of Schizoid Cognitions, the present author's two-scale STQ (modelled on the DSM-III criteria (American Psychiatric Association, 1980) for borderline states), and the Predisposition to Hallucination Scale devised by Slade and his colleagues, who have taken the slightly different approach of focusing on a single psychotic symptom, rather than sampling a range of schizotypal characteristics.

Standing somewhat apart from the other questionnaires are the psychoticism or P scales constructed by Eysenck & Eysenck (1976). These differ from the other scales in having been developed directly out of Eysenck's theory of personality. Consequently they purport to measure a person's *general* predisposition to any form of psychotic disorder, rather than schizophrenia in particular. Furthermore, the items in the published version, referred to in Table I, draw little from the clinical domain, focusing more on personality characteristics, especially of a socially deviant kind.

A question that naturally arises is how far these various scales relate to one another; since, despite the use here of the umbrella term 'schizotypy', it is already clear that they are unlikely to measure a unitary characteristic. To the author's knowledge there have been no systematic correlational or factor analytic studies in which all of the scales described have been included. Nevertheless, some conclusions can be drawn from three partially overlapping investigations: one by Chapman *et al* (1982), one by Muntaner & Garcia-Sevilla (1985), and an unpublished study conducted by Faily & Venables. The results broadly agree in suggesting that the various scales currently in use tap at least three separable components: perceptual and cognitive characteristics of a manifestly schizophrenic nature; feeling traits of an anhedonic kind; and deviant or antisocial behaviours and attitudes.

Thus, since 1972 considerable progress has been made in developing psychometric instruments for detecting psychotic traits in non-clinical populations. The existence of such traits in healthy adults now seems beyond reasonable doubt.

Experimental research

As mentioned earlier, all of the questionnaire scales just described have been used in studies attempting to characterise high-scoring individuals on experimental measures chosen according to their relevance to schizophrenia; mostly measures that have already been shown to discriminate clinically diagnosed schizophrenics from unselected groups of normal subjects or other psychiatric patients. The purpose of such research has been twofold: (a) to validate the questionnaires themselves, and (b) to throw further light on the aetiology of psychosis.

The domains of behaviour sampled and the experimental paradigms guiding particular studies have differed greatly, mirroring the equally variegated nature of research on the clinical syndrome itself. Three main approaches can be distinguished: psychophysiological, cognitive, and hemisphere function.

Psychophysiologial studies

In the argument of the case in 1972 for a nervous typological model of schizophrenia, particular reference was made to certain data, collected in the author's laboratory, suggesting that a unique feature of the psychotic nervous system might be its tendency to physiological 'dissociation', demonstrable empirically as a grossly altered sensitivity to sensory stimulation, inappropriate to the individual's prevailing level of tonic arousal. It had been suggested earlier (Claridge, 1967) that this might reflect some aspect of altered homeostasis in the nervous system, perhaps involving a weakening of inhibitory control.

In 1972 there was actually very little direct evidence that the characteristic just described might be a permanent feature of the nervous system in some healthy, but 'schizotypal', individuals. Since then, however, it has been possible to explore the idea in a series of interlocking studies having a common experimental strategy: the measurement, at varying levels of tonic arousal (electrodermal level), of individual subjects' sensory response, monitored with either EEG evoked potential or visual threshold procedures. To date, experiments have been conducted with drug-free schizophrenics (Claridge & Clark, 1982), the first-degree relatives of schizophrenics (Claridge *et al*, 1985), a rhesus monkey under LSD-25 (Claridge *et al*, unpublished), and normal subjects with high scores on an early version of the Eysenck P scale (Claridge & Birchall, 1978). In all of these cases the same unusual 'dissociation' of function was observed, when compared with the various control comparisons made. The findings would therefore strongly support the author's original suggestion that a dysregulated mode of CNS functioning, rather than altered reactivity *per se*, might be one important biological characteristic disposing to schizophrenia. This conclusion would be in line with that of Haier *et al* (1980), who found that psychiatric vulnerability, assessed in otherwise normal subjects, was best predicted not by a single biological indicator but by an altered profile of response which they interpreted as signifying an 'unbalanced' or poorly regulated mode of central nervous control.

In distinction to the studies just described, other workers have confined themselves to examining a *single* psychophysiological measure, in order to determine whether 'schizotypal' subjects, like schizophrenics, show an abnormality of 'arousability', usually as indexed by some aspect of electrodermal responsivity. In evaluating these findings it is important to bear in mind the great heterogeneity found on such measures among schizophrenics themselves, a fact articulated in the putative distinction made by Venables and his colleagues between 'responder' and 'non-responder' forms of schizophrenic syndrome (Gruzelier & Venables, 1975), and also mirrored in the differing findings reported by those workers who have studied high-risk children from a similar point of view: there both abnormal hyperresponsivity (Mednick & Schulsinger, 1968) and its opposite (Kugelmass *et al*, 1985) have been said to characterise such children.

Questionnaire-based studies using normal adults reveal the same picture. Thus, Nielsen & Petersen (1976) reported increased physiological responsiveness in subjects with high scores on their specially constructed scale of 'schizophrenism' (see Table I); while the opposite has been found by Simons (1981, 1982) using the Chapman anhedonia scales and by Robinson & Zahn (1985) using the published Eysenck P scale.

It is possible that the above findings reflect the use of scales tapping different aspects of 'schizotypy'; or alternatively, as suggested earlier, that schizotypy is characterised more by an *instability* of physiological reactivity, leading to extremes of response in either direction, depending on the conditions of testing (Claridge (1987) gives a fuller discussion of this point). Either way, the heterogeneity of psychophysiological response observed in these studies can at least be said to map well on to parallel data obtained with schizophrenic patients and genetically at risk children.

Cognitive studies

The relevant work here has been carried out against the background of the considerable research that has been done on the cognitive aspects of schizophrenia, in both patient and high-risk samples (see Nuechterlein & Dawson (1984) for a recent review). As in the clinical literature, it has been guided by several different paradigms.

One 'classic' approach, which continues a theme from the author's 1972 paper, has involved looking for evidence of the loosened or divergent styles of thinking that would be expected in appropriately selected normal subjects. Subsequently, Woody & Claridge (1977), using the Eysenck P scale and a standard battery of 'creativity' tests, demonstrated that high scorers were indeed more divergent. More recently a similar finding was reported by Miller & Chapman (1983), using the latter's scales in conjunction with a continuous word association task: subjects with high scores in Perceptual Aberration/Magical Ideation gave a larger number of idiosyncratic responses. Miller & Chapman's result converges closely on several similar observations in high-risk research, including a finding by Mednick and his colleagues who, using the same task, reported more deviant associations in the children of schizophrenic parents (Griffith *et al*, 1980).

Other approaches to the problem have drawn on more contemporary ideas in cognitive psychology that have inspired attempts in schizophrenia research to identify the stage or component of information processing which mediates psychotic symptoms. One hypothesis – that processing is slower at a very early stage of input – has received support from several studies using the 'backward masking' procedure, which tests the subject's efficiency in reporting a target stimulus presented at varying intervals after a strong, non-informational visual mask. Reduced efficiency on this task has been found right along the schizophrenic 'spectrum', including not only fully diagnosed schizophrenics and subjects with schizotypal personality disorders (Braff, 1981; Saccuzzo & Schubert, 1981), but also normal subjects with the schizotypal MMPI profiles referred to earlier (Steronko & Woods, 1978; Nakano & Saccuzzo, 1985).

Another view of information processing in schizophrenia is that offered by Frith (1979), who has argued that schizophrenics have difficulty in limiting the contents of consciousness, due to weak inhibitory selection of information at the early, preconscious stage of processing. An appropriate methodology for testing this hypothesis is that of 'priming', in which the subject's response to a probe target (e.g. a word) is manipulated with a briefly presented prior stimulus. Predictable differences have been found using various applications of this general technique, in studies of schizophrenic patients (Bullen, 1982) and of normal subjects with high scores on the Eysenck P scale (Bullen & Hemsley, 1984) and on the schizotypal personality scale of the author's STQ inventory (Beech & Claridge, 1987). The last experiment, one of a number currently in progress in the author's laboratory, was specifically designed to test *negative* priming, which is thought to tap inhibitory effects in selective attention (Tipper, 1985). The results of all of these studies support the idea that schizotypal individuals, like schizophrenics, do indeed show weakened inhibition during information processing.

Another, rather different line of research is that pursued by Slade and his colleagues into the possible mechanisms of hallucinations. As noted earlier, their questionnaire concentrates specifically on disposition to hallucinations as a normal characteristic, and their experimental investigation of the new scale has had a corresponding focus, derived from signal detection theory (Bentall & Slade, 1985*a*). Carrying out an analysis of normal subjects' performance on an auditory detection task, they showed that high scorers on their hallucinatory disposition scale differed significantly in perceptual bias, such that they were more likely to report that a target stimulus was there when it was not. Notably, Bentall & Slade found an identical effect in hallucinating, compared with non-hallucinating, schizophrenic patients.

Studies of hemisphere function

The third field of experimental research to be considered here is relatively recent, although the clinical evidence from which it is derived has been extensively documented (Walker & McGuire, 1982; Gruzelier, 1983). The possibility that the unusual cerebral asymmetries observed in schizophrenic patients – particularly with reference to the processing of linguistic material – may find their counterpart in normal individual differences in laterality is one that has been explored recently by the author and colleagues, in relation to their scale of schizotypal personality. These studies, with one exception, have used a divided visual field procedure to present various kinds of stimuli, including nonsense syllables (Broks, 1984) and single letters (Rawlings & Claridge, 1984). It has been found that highly schizotypal normal subjects are indeed comparable to schizophrenics in showing either weakened or even reversed laterality, a particular feature being their relatively efficient processing of such material when it is routed first to the right hemisphere.

Another investigation in this same series looked at the auditory modality (Broks *et al*, 1984). The procedure adopted here was the story comprehension test developed by Green and his associates and used by them to demonstrate, among other things, that both schizophrenics and the children of schizophrenics show poor recall of binaurally, compared with monaurally, presented prose (Green *et al*, 1983). Of two experiments by the author and colleagues in normal adults, one showed exactly the same effect for high schizotypes. The other, using slightly different stimulus material, did not, although it did confirm part of the findings of the author and his associates in the visual modality; namely that schizotypal individuals show reduced asymmetry, due to a superior performance in (in this case) the left ear.

In addition to the similarities, there are also marked differences between schizophrenics and normal schizotypes; notably that the former regularly perform poorly and the latter in general perfectly well when linguistic material is presented through what is usually regarded as the most efficient route; that is, through the right ear or right visual field. The view on this currently held by the author and his co-workers would draw on ideas such as those put forward by Randall (1980), Wexler (1980) and others and suggest that schizophrenia may be associated with *enhanced* communication between the two halves of the brain, perhaps due to decreased inhibition. In the normal schizotype this might not be disadvantageous but might become increasingly so under certain conditions or when present to an extreme degree.

The schizophrenias as nervous types – 1987

From the studies just reviewed, the theory put forward in 1972 now looks even more substantive. There seems to be irrefutable evidence that logically related biological, cognitive, and personality characteristics ascribed to schizophrenia can also be observed in some healthy individuals. Furthermore, the surrounding evidence, especially from genetics research, indicates that these characteristics constitute inherited traits predisposing to the disorder.

Nevertheless – although this is equally true of research on patients – a unifying theme has still to emerge; in the sense of one sure idea being found which can account for data that crosses such varied domains as psychophysiology, cognitive psychology, and the neuropsychology of hemisphere function. It is, however, noted with interest that all three of these approaches have, in one guise or another, led to the conclusion that a crucial feature might be some deviation in the setting-point for mechanisms that exert inhibitory control over psychobiological function. The exact form that this might take, or the exact level in the nervous system at which it might operate, is of course entirely speculative; but Johnson's (1985) recent suggestion that some aspect of 'feed-forward' inhibition could be involved is very persuasive.

There are also two other problems not as yet entirely resolved. One concerns the fact that, at a descriptive level, schizotypy seems not to be a unitary dimension, but to consist of several subcomponents which between them encompass personality traits of social nonconformity as well as more manifestly psychotic characteristics. A related question is whether, and if so how, such components map on to the clinical syndromes themselves. Do they, for example, either singly or in varying combinations, form dispositions to different varieties of schizophrenic reaction? A further possibility that must be considered is that the term 'schizotypy' is already too narrow and that the traits discussed here encompass the entire range of psychosis. For there is increasing reason to believe that the schizophrenias and the affective psychotic disorders are aetiologically less distinct than was once believed (Claridge, 1985; Crow, 1986).

Although a precise knowledge of the 'schizotypal nervous system' is still lacking, the model developed in this and the 1972 paper does at least establish a *general principle* for future research on the aetiology of schizophrenia; namely the need to complement knowledge about normal variations in behaviour and brain functioning with observations about possible exogenous biological and social factors that help to trigger the symptoms of illness in the predisposed individual. The interfacing of these two domains might ultimately prove crucial to understanding. After all, to recall the analogy with the physical systemic diseases, it is unlikely that the causes of stroke or heart disease could ever have been properly understood without knowledge of normal vascular function.

Adopting the strategy just described would place more burden than hitherto in schizophrenia research on the study of healthy, but identifiably predisposed, individuals who might provide clues to aetiology not available, or obscured, in the currently psychotic person. That conclusion is of course identical to that which first inspired longitudinal high-risk studies of schizophrenia (Mednick & McNeil, 1968) and which continues to do so. It is therefore satisfying that some of the findings of the cross-sectional experiments referred to here converge on the results of those projects. Indeed, there are already signs of an increasingly blurred distinction between high-risk research proper and research carried out from the viewpoint of normal differential psychology (Siever *et al*, 1985). The fact that some of this work (e.g. Haier *et al*, 1987) is beginning to make use of the newer brain imaging techniques – albeit in the quest for functional differences rather than discrete lesions – might also help in the narrowing of the other gap in schizophrenia research which it has been the purpose of this paper to encourage: that between 'disease' and 'dimensional' theories of the disorder.

Post-mortem Study of Chronic Schizophrenic Brains

BENTE PAKKENBERG

Volume measurements were carried out on 29 brains from institutionalised, chronic schizophrenic patients and 30 age and sex-matched controls using a stereological method. The volumes of the total fixated brain, the hemispheres, the cortex, and the central grey matter of the schizophrenic brains were significantly reduced while the volumes of the ventricles were significantly enlarged compared with the control group. The patients had been diagnosed by a psychiatrist on the basis of their case records as having either a Type I or Type II syndrome according to the symptoms they presented in the first years of their disease. The Type II patients were found to have significantly enlarged ventricles compared with the Type I patients.

Kraepelin in 1896 and Bleuler in 1916 expressed the view that a neuropathological basis of schizophrenia would eventually be found. Nevertheless, Winkelman & Book (1949), who reviewed a number of histopathological papers written from 1924 to 1944, could state in 1948 that "excellent investigators have concluded that dementia præcox has no organic foundation". They reported the results from Dunlap (1924), Spielmeyer (1930), Bamford & Bean (1932), Peters (1937), and Scheidegger (1942), who found no changes in the post-mortem brains from schizophrenia patients which could not be duplicated in 'normal' controls. They also reported investigations showing unspecific findings in schizophrenic brains. Watanabe (1934) found acute and severe nerve cell disease in acute cases of schizophrenia and fatty changes in nerve cells in Ammon's horn. Miskolczy (1937) reported disappearance of the cortical neurones of the frontal, parietal, and temporal regions, lipoid infiltration of the nerve cells, and mild glial proliferation. Winkelman & Book (1949) found focal and general loss of nerve cells, degenerative changes, and fairly uniform hyperplasia and hypertrophy of macroglia in ten selected cases of schizophrenia from a group of 60.

Since then, various studies have been carried out on schizophrenic patients. Using encephalography, Huber (1957), Haug (1962), and Asano (1967) found enlarged ventricles in schizophrenic patients. In 1976, Johnstone *et al*, from computerised tomographic (CT) head scans, reported significantly enlarged lateral ventricles in chronic schizophrenic patients.

The histopathological findings and the observation of enlarged ventricles in some schizophrenic patients have been a continuous encouragement to seek further knowledge of this complex disease.

In 1983, Weinberger *et al* made a selective review of recent post-mortem studies, pneumoencephalographic studies and CT findings. They concluded that qualitative non-specific pathology of the limbic system and the diencephalon is associated with many cases of schizophrenia. Mild, but statistically significant, ventricular enlargement consistent with, but not diagnostic for, limbic or diencephalic pathology is the most prevalent finding, along with anterior cerebellar vermis atrophy, atypical lobar asymmetries, and regional decreases in brain density, the clinical relevance of which awaits clarification.

In the work of Kovelman & Scheibel (1986), attention is directed to the biological substrates of schizophrenia, including their own observation of varying degrees of structural disorganisation and disorientation of the hippocampal pyramidal cells making up the cellular layer of the cornu ammonis. In their conclusion they emphasise the structural and physiological studies, which are mutually persuasive in their indication of left hemispheric dysfunction, deficits or interhemispheric integration and limbic system involvement.

Undoubtedly, psychiatric research has often presented positive findings, but few of these have led to a clearer understanding of the pathogenesis of psychiatric illness or to more effective treatment. In 1982, Crow hypothesised that schizophrenics represent two symptom groups, each reflecting a different underlying disease process. The constellation referred to as the Type I syndrome is characterised by such positive symptoms as hallucinations, delusions, and thought disorders. This type of illness, most often seen in acute schizophrenia, shows a good response to neuroleptics and an absence of intellectual impairment. The outcome is described as reversible, and the postulated pathology could be due to a disturbance in the dopamine system. The Type II syndrome is characterised by such negative symptoms as affective flattening, poverty of speech, and loss of drive. This illness has a more chronic course and a poor response to neuroleptics, and the patients may develop intellectual impairment. The outcome may be irreversible. While the Type I syndrome is not associated with enlargement of the ventricles, the brain cell loss and structural changes in the Type II syndrome have been related to cerebral atrophy. While the two syndromes may represent independent dimensions of pathology, they do not constitute separate diseases. Patients may have symptoms of both types, either at the same time or sequentially.

To date, there have been many investigations of quantitative observations in schizophrenic patients, but less attention has been paid to post-mortem quantitative findings. The aim of this study was to determine the volume of the cortex, white matter, ventricles and central grey matter in post-mortem brains of chronic schizophrenics compared with control brains in a double-blind examination using a stereological method (Regeur & Pakkenberg, in preparation), and to relate the results to the positive/negative symptoms of the patients, as well as other parameters.

Method

Material

Twenty-nine brains from chronic schizophrenic patients were collected from two psychiatric wards over a period of 18 years (1967–1985) and matched according to age and sex with 30 brains from control patients collected in the period 1973–1985 from four pathology department wards in Copenhagen. The brains were removed within 72 h after death and kept in 10% formalin for at least 5 months to ensure a stable volume (Haug *et al*, 1984). Exclusion criteria for schizophrenic patients were strokes or tumours in the central

1. BLM = bucca-lingua-masticatory syndrome.

nervous system (CNS) and drug abuse. For controls, exclusion criteria were death from cancer, any history of alcohol or drug abuse, earlier or present strokes, tumours or infections in the CNS, any record of dementia, and being comatose for more than 24 h prior to death. All relevant parameters are shown in Table I.

Table II shows the general information concerning the patients.

A psychiatrist had classified the patients as Type I or Type II on the basis of their symptoms during the first years of their illness. These results are shown in Table III, with the respective diagnosis, and whether or not the patients were demented in their final years, and whether or not there was a family history of schizophrenia.

Nine patients had seven first-degree relatives who were schizophrenic and ten second-degree relatives with this diagnosis. Nine first or second-degree relatives suffered from such other psychiatric diseases as paranoid psychosis, manic–depressive illness, or anxiety neurosis. Eight of the nine patients with affected relatives had a paranoid form of schizophrenia.

Five first or second-degree relatives committed suicide. In one case, a female patient had a father, an uncle and two cousins who were schizophrenic; two uncles and an aunt committed suicide.

Socially, most of the patients were not very well integrated. Only one finished high school and none were academics. Ten of the 29 had been married. The women had mostly been employed as domestic help, the men as unskilled labour. Four patients had for a time had clerical work and one had been a musician; none had had employment subsequent to admission to a psychiatric ward, except for the musician.

One patient had had a history of lues cerebrospinalis, another had been an alcoholic when he was young. Thirteen patients developed dyskinesia, all of them oral dyskinesia, and five of them additional symptoms such as hyperkinesia of the head, body, or extremities and/or hand tremor. All 13 had received high-dosage neuroleptics (Table I).

Table IV shows the general information for the controls.

Procedure

The brains were weighed and fixed. After at least 5 months in 10% formalin, the brains were weighed again, the

meninges were removed, and the cerebellum and brain stem cut off corresponding to the upper level of the pons. The brains were incubated in 20% gelatin in 2% aqueous phenol, and then placed for 7 days in a refrigerator at 4°C, after which the surplus of gelatin was trimmed off, leaving the brain with a gelatin coat approximately 2 mm thick. The brains were then cut in coronal slices 6 mm thick, with a cutting apparatus specially designed for the purpose. Each slice was photographed, colour slides were produced, the slides were placed in a Kodak Carousel S-AV, and the picture was projected down on to a table by way of a mirror. Each slice was point-counted using a double-lattice grid with 64 coarse points and 1024 fine points (Weibel, 1979). The length of the brain was measured leaving out the first and last slice, and the volumes of the hemispheres, cortex, white matter, ventricles and central grey matter were determined using Cavalieri's theorem (1966):

$$\mathrm{vol}_{\mathrm{cerebrum}} = \bar{t} \times a(\mathrm{frame}) \times \Sigma P$$

where

$$\bar{t} = \frac{\text{length of brain} - (\text{first} + \text{last slice})}{\text{number of slices} - 2}$$

a(frame) = area per point on the grid, corrected for magnification

ΣP = the total number of points falling on the object.

The coefficient of error for the total procedure is 0.028.

Statistical methods After ensuring normal distribution (χ^2 of fit), differences between groups were tested by comparing two regression lines, schizophrenic versus control, taking into account the fact that brain volumes in humans are correlated to body height. Since this was the case for all parameters except the volume of the ventricles, the ventricle volume was tested by two-tailed Student's t-test. Only $2P$ values less than 0.05 were considered statistically significant.

Results

There was a statistically significant difference between the controls and the schizophrenics as regards total brain weight (controls $\bar{x}_c = 1314$ g, $CV_c = 0.10$; schizophrenics $\bar{x}_s = 1205$ g, $CV_s = 0.15$), $2P = 0.0018$; the hemispheres ($\bar{x}_c = 1046$ ml, $CV_c = 0.13$, $\bar{x}_s = 959$ ml, $CV_s = 0.16$), $2P = 0.015$; the cortex ($\bar{x}_c = 578$ ml, $CV_c = 0.16$, $\bar{x}_s = 510$ ml, $CV_s = 0.16$), $2P = 0.0030$; central grey matter ($\bar{x}_c = 47.9$ ml, $CV_c = 0.14$, $\bar{x}_s = 44.5$ ml, $CV_s = 0.16$), $2P = 0.048$; and the ventricles ($\bar{x}_c = 26.3$ ml, $CV_c = 0.37$, $\bar{x}_s = 35.1$ ml, $CV_s = 0.47$), $2P = 0.024$.

Fourteen patients had been classified as Type I and twelve patients as Type II, while three were a mixture of Type I and Type II (Table III). The volumes of the ventricles were significantly smaller ($2P = 0.015$) in the Type I patients than in the Type II patients. There was no statistically significant difference in the volumes of the white matter ($\bar{x}_c = 395$ ml, $CV_c = 0.11$, $\bar{x}_s = 370$ ml, $CV_s = 0.23$) ($2P = 0.23$) in the schizophrenic brains compared with the controls. In the 18 demented patients, the ventricles did not differ significantly in size from those of the other schizophrenics ($2P = 0.17$), nor did the cortex volume from the demented patients differ from that of the other schizophrenics ($2P = 0.86$).

The 13 patients who developed hyperkinesia had neither significantly larger ventricles ($2P = 0.92$) nor smaller central grey matter ($2P = 0.83$) than the rest of the schizophrenic group. There was no significant difference in the length of treatment in the patients who developed dyskinesia compared with the rest of the schizophrenics ($P = 0.78$). There was no significant difference in the height ($P = 0.80$) or weight ($P = 0.14$) of the control patients compared with the schizophrenic group. The length of neuroleptic treatment was unrelated to the Type I/Type II diagnosis ($P = 0.96$). The cortex of patients treated with ECT showed no significant difference from that of the rest of the schizophrenics ($2P = 0.88$).

The ventricles of the six patients treated with insulin-induced hypoglycemic coma were of normal size ($P = 0.89$) compared with the rest of the schizophrenic group. Other investigators have found smaller ventricles in such patients (Johnstone *et al*, 1976). The lack of confirmation of their results could be due to the small number of insulin-treated patients in this study.

The nine patients who had a first or second-degree relative with schizophrenia did not have significantly enlarged ventricles ($P=0.48$) compared with the rest of the schizophrenic patients.

The size of the ventricles in the younger controls ($n=9$, age 41–65 years with a $\bar{x}_{c,young}=20.8$ ml) was significantly smaller ($P=0.024$) than in the older controls ($n=21$, age 66–95 years, $\bar{x}_{c,old}=29.6$ ml). In the schizophrenic group there was no difference between the size of the ventricles in the younger individuals ($n=6$, age 41–65 years, $\bar{x}_{s,young}=36.6$ ml) and the older ones ($n=23$, age 66–95 years, $\bar{x}_{s,old}=34.9$ ml), $P=0.83$.

There was no statistically significant difference in the size of the ventricles between the paranoid and non-paranoid schizophrenic patients ($P=0.50$).

Discussion

For many years, the most interesting observation in schizophrenic patients has been the finding of enlarged ventricles, using CT head scans. In the present study, the total brain weight and the volumes of the hemispheres, cortex, and central grey matter were found to be significantly smaller and the ventricles significantly enlarged in this group of institutionalised, chronic schizophrenics. The only parameter not affected was the white matter.

The patients in this study were relatively old. Although they had been severely affected by their disease, it had had no substantial influence on their lifespan. In this respect it differed from many other diseases with serious brain disturbances (e.g. Alzheimer's disease, multiple sclerosis, Jacob–Creutzfeldt disease, Huntington's chorea). In contrast with these degenerative brain disorders, no specific changes (Alzheimer, multiple sclerosis), specific agents (Jacob–Creutzfeldt) or specific brain localisation (Alzheimer, Huntington's chorea) were found. The present findings were therefore not surprising, but confirmed the impression of a widespread effect on the central nervous system.

A positive correlation has been shown to exist between body height and brain weight; such a correlation was not found between body weight and brain weight (Pakkenberg & Voigt, 1964). For this reason all parameters in the two groups, except the ventricular volume, were compared by way of regression lines, plotted with body height on the x-axis and the brain volumes on the y-axis. The lack of correlation between body height and ventricular volume in the present study was unexpected (Gyldensted, 1977), but could be due to the rather small number of brains.

The metabolic investigations of schizophrenic patients have shown different results. An increase in dopamine receptor density assessed by spiperone binding has been found in post-mortem brains of schizophrenic patients (Owen *et al*, 1978). In a study on a small number of patients, dopamine receptor binding as measured with ^{11}C-methylspiperone and positron emission tomography (PET) gave no significantly different ratios for the schizophrenic patients (Herold *et al*, 1985).

Elevated brain D2 dopamine receptors have been found in both drug-naive and drug-treated schizophrenics using PET (Wong *et al*, 1986). Measurements of regional cerebral blood flow (CBF) have not been unequivocal (Nilsson *et al*, 1985; Goldstein *et al*, 1985), but there seems to be a trend toward decrease of CBF in frontal and prefrontal regions of schizophrenics (Geraud *et al*, 1985; Warkentin *et al*, 1985; Devous *et al*, 1985).

The procedure for obtaining CT scans can be standardised, but interpretation of the scans themselves presents considerable methodological problems. Jacoby & Levy (1980) have pointed out the difficulty of making accurate determinations of the ventricular boundaries from the scans (partial volume effect). They concluded that ratio measurements, which are most often used, are probably as useful as any other type of analysis. However, from the perspective of a field where gross anatomical changes demonstrated at autopsy are the *sine qua non* for validating radiologically observed changes, CT scan findings from schizophrenic patients should be verified by autopsy (DiChiro, 1983).

The present study has demonstrated enlargement of the ventricles in the brains from schizophrenic patients – an observation which accords with the conclusions of other investigators using CT head scans from schizophrenics (Johnstone *et al*, 1976; Andreasen *et al*, 1982; Nasrallah *et al*, 1982*a*).

The observation that the ventricles from Type II patients are bigger than those from Type I patients corresponds with the results of Andreasen *et al* (1982), who found that 16 schizophrenic patients with ventricular enlargement tended to have a preponderance of negative symptoms and impaired functioning on tests of the sensorium, while 16 schizophrenic patients without ventricular enlargement tended to have a preponderance of positive symptoms and a normal sensorium. This was not confirmed, however, by Nasrallah *et al* (1982*a*), who found in a study of 55 chronic male schizophrenics that large cerebral ventricular size in schizophrenia was not related to age at first admission to hospital, duration of treatment, pre-morbid adjustment, response to antipsychotic drug treatment, cognitive functioning, or the presence of positive or negative symptoms. In the present study, not all patients with the Type II syndrome had large ventricles, but the difference was significant for the total group of Type II patients compared with the Type I patients. The symptoms of the Type II syndrome patients remained more or less unchanged throughout life. This supports the view of Crow (1982), who points out that it is unusual for patients who have once acquired negative symptoms to lose them, perhaps because such symptoms are closely associated with structural changes in the brain. Weinberger (1984) suggests that the difference in ventricular size in schizophrenic patients could reflect pathology that is not qualitatively distinct but quantitatively different. Patients with CT findings may, thus, represent one extreme of a pathological continuum. It would then follow that the more pathology, the more CT evidence of it, and the poorer the prognosis.

Weinberger *et al* (1982) have shown that 7 out of 35 patients with first-episode schizophreniform disorders had cerebral ventricles larger than those expected for the second and third decades of life. Thus, the enlargement of the ventricles predates the acute illness, possibly by a period of years. The size of the ventricles differs considerably, not only in the schizophrenic brains but in the control group as well. Possibly, the size of the ventricles in an individual is a predisposing factor for the type of schizophrenia which develops. If the ventricular size is a predisposing factor, and an individual with normal-sized ventricles becomes schizophrenic, this patient, most probably, will present positive symptoms, and vice versa.

This does not limit the occurrence of atrophy to only some schizophrenics. The entire distribution of ventricular size for the schizophrenic brains shows a general upward drift. The same observation was made by Weinberger *et al* (1982) using CT head scans of 35 patients with schizophreniform disorders and 17 chronic schizophrenics. Atrophy thus seems to occur in most patients, and is simply more pronounced and has a greater probability of being observed in those patients with large ventricles before the onset of their illness. This could account for the observation, also in the present material, that some Type I patients develop negative symptoms during life. It does not explain, however, that in some cases patients with small ventricles make a schizophrenic debut with typical Type II syndrome symptoms, unless these patients had even smaller ventricles before the onset of the disease.

The two follow-up investigations on schizophrenic patients – Haug (1962) using pneumoencephalography on 31 patients after a period of 0.1–4.5 years, and Weinberger & Wyatt (1982) using CT scans on six patients over a period of 2–3 years – have not revealed any change in ventricular size. It would be of interest to have a longer follow-up period on young schizophrenic patients.

It has been pointed out (Jacoby & Levy, 1980) that patients over 50 years of age have a greater probability of presenting cerebral atrophy. This, combined with the fact that 62% of the schizophrenic patients were demented in old age, a condition associated with cerebral atrophy, could be a possible source of misinterpretation of results. However, no statistically significant difference was found between the volume of the cortex from the demented patients compared with the non-demented, given a $2P$ value of 0.86. The ventricles in the 13 demented patients did not differ in size from those in the rest of the schizophrenic brains.

Studies have shown that cerebral ventricles usually are smaller post-mortem than in life. Agonal pre-mortem events, coincident illness, brain oedema, and post-mortem extraction and fixation procedures may all obscure pre-mortem ventricular enlargement, especially if such enlargement is only modest (Messert *et al*, 1972). But still the volumes of the ventricles differed significantly in the schizophrenics compared with the controls.

There was no difference in the length of neuroleptic treatment in the Type I patients compared with the Type II patients. This supports the observation that the size of the ventricles does not have a great influence on the possible benefit of drug treatment. Weinberger *et al* (1980) found a significantly better response to neuroleptics in ten schizophrenic patients with normal ventricular size tested with Brief Psychiatric Rating Scale (BPRS) scores, compared with ten schizophrenic patients with enlarged ventricles. However, they concluded that a CT scan finding, no matter how dramatic, should never take precedence over a clinically indicated trial of therapy. Their clinical experience suggested that most patients with enlarged ventricles do benefit from drug therapy, and that this benefit may be clinically valuable, even if not reflected in a significant change in BPRS score.

In recent years the importance of inheritance has been discussed. An estimated 4.2–12.3% risk of schizophrenia in first-degree relatives of schizophrenic probands was found by Rosenthal (1970) and Slater (1938). In a study by Kety *et al* (1971), 33 adoptees with a diagnosis of chronic schizophrenia, acute schizophrenic reaction, or borderline schizophrenia were found among a sample of 5483 adoptees. A significantly higher than usual prevalence of schizophrenia-related illness was found among the biological relatives of adopted schizophrenics, but not among their adoptive relatives. As pointed out by Pope *et al* (1982), many studies, particularly American, have used a broad definition of schizophrenia, such as the DSM-II. Thus, many earlier familial studies of schizophrenia probably contained cases that would no longer be considered schizophrenic. Pope *et al* found no schizophrenic relatives in 199 first-degree relatives of DSM-III schizophrenic probands ($n = 39$), suggesting a zero prevalence. Abrams *et al* (1983) found in a group of 30 schizophrenic probands an age-corrected morbidity risk in first-degree relatives of 1.61%. They conclude that the case for familial transmission of narrowly defined schizophrenia is weak. Tsuang *et al* (1980) found a morbidity risk of 3.2% in first-degree relatives in a study of 200 schizophrenics.

In the present material, 9 out of 29 schizophrenics had affected relatives. Including both first and second-degree relatives, 17 had a schizophrenic diagnosis. No attempt has been made to trace back the affected relatives, since many died more than half a century ago. No personal interviews have been conducted with any of the relatives. The schizophrenic diagnosis is limited to the information given in the case records, and this could account for an over-representation. Yet the majority of these relatives spent their lifetimes in a psychiatric ward. This would tend to support previous reports of a genetic component in this condition, at least in severe cases of the disease.

Nasrallah *et al* (1982*b*), in a study of 42 chronic schizophrenics, found a difference in ventricular size, using bifrontal and bicaudate diameters on CT head scans, between paranoid and non-paranoid patients. Significantly more paranoid patients were found to have ventricles whose diameters exceeded the control mean by more than 1 s.d. In the present material, 18 of 29 patients had a diagnosis of schizophrenia paranoides. There was no significant different in the size of the ventricles in the two groups.

Thirteen patients developed dyskinesia. The symptoms appeared 1–26 years from the start of treatment. There was no relation between the size of the ventricles and the development of dyskinesia. Patients with large ventricles had no greater probability of developing this condition. In fact, only three patients with Type II syndrome developed dyskinesia. The size of the central grey matter was almost identical in the two groups.

According to previous studies of the normal population, there exists a positive correlation between ventricular size and age. Nybäck *et al* (1982), however, did not find such a correlation between lateral and third ventricular sizes and age, in their group of definite schizophrenics. They suggest that the normal age-related enlargement of the ventricular system may be obscured in some way in patients with schizophrenic psychosis.

In the present material, the same result was found. The size of the ventricles was significantly smaller in the younger control group than in the older group. This was not the case in the two schizophrenic groups: the lack of correlation was not only due to relatively wide ventricles in the younger patients, but also to relatively small ventricles in some of the older ones. Again, the atrophy that occurs in schizophrenics seems to appear early in the development of the disease.

The present study has shown significant reduction of almost every macroscopic parameter in a group of schizophrenic brains. However, this does not lead to a better understanding of the underlying microscopic changes in the brain. The dopamine hypothesis still represents the most lasting theory of schizophrenia, pointing toward a pathophysiological condition in the basal ganglia and limbic system. For this reason, more specified quantitative investigations of the limbic regions in post-mortem schizophrenic brains will be of interest.

Presentation: Prothiaden is Dothiepin Hydrochloride B.P. an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 × 75mg £4.00 as at 1st Oct. 1987. **Product Licence Numbers:** PL0014/5941, PL0014/0209. The Boots Company PLC, Nottingham, England. Further information available on request. ETH 1174/9/87

A common cry for help. Perhaps triggered by one or more factors. But, all too often, diagnosis of the root cause of their problem is clouded by anxiety or somatic symptoms masking the underlying condition. You can trust Prothiaden to brighten up their lives.

Millions of prescriptions make Prothiaden the UK's most widely prescribed antidepressant. After 18 years of clinical experience, Prothiaden's safety is known. Its performance unsurpassed.

o, paint a brighter picture for our elderly patients who find they can't cope – with a prescription for Prothiaden.

BOOTS

Psychotropics

Prothiaden

Dothiepin Hydrochloride B.P.

Brightens the outlook for millions of lives

From Clinic to Community

CLOPIXOL®

zuclopenthixol dihydrochloride/decanoate

TABLETS • INJECTION • CONC INJECTION

PRESCRIBING INFORMATION

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.

Indications Psychoses.

Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses. Not recommended for children.

Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.

Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerence to other neuroleptics. Pregnancy (relative). Use with caution in patients with Parkinsonism, severe arteriosclerosis, senile confusional states; serious renal, hepatic or cardiovascular disease.

Overdosage Overdosage should be treated by gastric lavage.

Package Quantities and NHS Price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00.

PL Nos 0458/0027,0028,0029. PA Nos 115/5/3,4,6.

CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.

Indications Psychoses, especially schizophrenia.

Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.

Not recommended for children.

Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.

Contraindications Comatose states.

Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.

Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur. (b) By sedation (with benzodiazepines) in the unlikely event of agitation or excitement. (c) By noradrenaline in saline intravenous drip if the patient is shocked.

Package Quantities & NHS Price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23.

PL Nos 0458/0017,0041. PA Nos 115/5/1,5,7

The Copenhagen High-Risk Project

The Diagnosis of Maternal Schizophrenia and its Relation to Offspring Diagnosis

Å. JØRGENSEN, T. W. TEASDALE, J. PARNAS, F. SCHULSINGER, H. SCHULSINGER and S. A. MEDNICK

The Copenhagen longitudinal high-risk study of offspring of 129 schizophrenic mothers commenced in 1962. At that time, the mothers were diagnosed according to contemporary Danish criteria. We have re-examined all of the hospital records of these mothers: 108 (84%) fulfil present-day DSM-III criteria for schizophrenia and 95 (74%) were diagnosed as paranoid schizophrenic according to ICD-8 criteria. In a follow-up at mean age 24, the offspring of the paranoid schizophrenic mothers were themselves found to be less frequently schizophrenic (5%) than were the offspring of non-paranoid schizophrenic mothers (29%).

Longitudinal high-risk studies have long been advocated in the investigation of the aetiology and pathogenesis of schizophrenia (Mednick & McNeil, 1968), and a number of such studies are now under way (Watt *et al*, 1984). The earliest of these was initiated in Copenhagen by Mednick & Schulsinger (1965) in 1962 and is still continuing. The high-risk group of this study comprises children of schizophrenic mothers.

Strauss (1984) has observed that rigorous diagnosis of parental schizophrenia is critical to high-risk longitudinal research. Diagnostic uncertainty could compromise many years of work. A particular problem facing longitudinal studies is that of changing diagnostic criteria through time. In the years since the 1962 inception of the Copenhagen study, several systems of diagnostic criteria for schizophrenia have been proposed, with the aim of increasing the reliability of the schizophrenia diagnosis. Thus, according to the criteria listed in ICD-8 (World Health Organization, 1967), the diagnosis of schizophrenia is based on the presence of described typical symptoms and symptom patterns but it is not clearly operationalised. In contrast, DSM-III (American Psychiatric Association, 1980) does provide clear operational criteria for schizophrenia. The concept of schizophrenia in DSM-III is rather conservative, with emphasis on duration.

The purpose of the present study has been to perform DSM-III and ICD-8 rediagnoses of maternal schizophrenia in the Copenhagen high-risk study, and to examine the association of these maternal diagnoses with the diagnostic outcome of the offspring for whom follow-up diagnoses according to ICD-8 have already been made (Schulsinger, 1976).

Method

The high-risk sample was initially derived by identifying all women who were admitted to hospital for severe psychosis within the vicinity of Copenhagen, and who had children in the age range 10–18. Their hospital records were read by one of us (FS), who selected those meeting diagnostic criteria of schizophrenia. The criteria at that time followed those of the Danish Psychiatric Association and were not precisely operationalised, but they were anchored in the Bleulerian concept of schizophrenia; thus they relied heavily on the presence of autism and formal thought disorder. In addition to these psychopathological criteria, it was required that the mothers should have had either at least five years in hospital; or at least three separate periods in hospital, each of at least three months' duration, with no sign of improvement during discharge; or an extended period in hospital plus a certified State Invalid Pension for schizophrenia.

The present rediagnosis of the 129 mothers according to the criteria of DSM-III and ICD-8 was carried out in connection with an extensive collection of data concerning the mothers. Employing information from the Danish central psychiatric register (Dupont *et al*, 1974), available case records from all admissions of the mothers to psychiatric hospitals and departments up to 1975 were obtained. The median number of admissions was 6.3 and the median total time in hospital was 28 months. In almost all cases this constituted considerably more record information on the mothers than had been available at the inception of the project in 1962.

The records were read by the senior author, who completed a precoded data schedule while remaining blind with respect to the diagnosis of the offspring. The schedule contained items covering the following areas: family history of mental illness; childhood background; premorbid personality traits; social adjustment and psychopathology; course of disease; social adjustment during disease; treatment; response to treatment, including side-effects; and maternal functioning. The Syndrome Check List (Wing

TABLE I
ICD–8 and DSM–III diagnoses for the mothers

ICD–8 diagnosis	*DSM–III schizophrenia*		
	Positive	*Negative*	*Total*
Schiz. simplex	2	0	2
Schiz. hebephrenic	13	0	13
Schiz. paranoid	84	11	95

et al, 1974) was used for scoring the psychopathology at each admission separately.

The mothers were diagnosed as schizophrenic according to DSM–III and/or ICD–8 if, at some time during their lives, they fulfilled the criteria of these diagnostic systems. For the ICD–8 diagnoses we used the *Glossary of Mental Disorders and Guide to Their Classification for Use in Conjunction with ICD–8* (World Health Organization, 1974). With respect to schizophrenia, such diagnoses are thereby equivalent to ICD–9. The ICD–8 diagnosis of schizophrenia was supplemented by a subtype diagnosis based on the symptomatology of the first phase of the schizophrenic disease.

In 1972–1974, a ten-year follow-up psychiatric assessment was undertaken of the 207 high-risk offspring of the 129 mothers, together with a matched control group comprising 104 subjects in whom neither the parents nor the grandparents were known to be psychiatric patients (Schulsinger, 1976). At that time, these offspring were between 18 and 30 years old (mean 24 years). On the basis of this assessment a clinical diagnosis was made by one of us (HS) according to the ICD–8 criteria. Since our present concern is with the relationship of the offspring diagnoses to the maternal diagnoses, the control group is not used here. For the purpose of statistical analysis the high-risk offspring diagnoses have been grouped into the following four categories: schizophrenia, borderline schizophrenia (corresponding to the DSM–III schizotypal personality disorder), other mental illnesses, and no mental illness. A total of 173 of the high-risk offspring completed the 1972–1974 assessment. To the 13 children diagnosed as schizophrenic on the basis of this assessment we have added two subjects who were already deceased at that time, but who could be posthumously diagnosed as schizophrenic on the basis of hospital record information.

Results

Table I shows the distribution of DSM–III (positive or negative for schizophrenia) and ICD–8 subtype diagnoses for the 129 mothers. Three mothers did not fulfil the schizophrenia diagnostic criteria of either DSM–III or ICD–8. According to the latter criteria, two of these suffered from paranoid states, while the third had a paranoid psychosis subsequent to amphetamine intoxication. On DSM–III criteria they were diagnosed as schizophreniform disorder, paranoid disorder followed by major depressive disorder at a later admission, and paranoid disorder respectively.

A further 18 mothers fulfilled the ICD–8 criteria, but not those of DSM–III. Of these, ten were diagnosed as atypical psychoses, with an onset of disease later than 44 years; but, this criterion apart, they all fulfilled the other DSM–III criteria for schizophrenia. The DSM–III diagnoses for the remaining eight mothers were: two schizophreniform disorders, two schizoaffective disorders, schizoaffective disorder followed by major depressive disorder, paranoid disorder, obsessive-compulsive disorder followed by atypical personality disorder, and schizotypal personality disorder. It is noteworthy that, according to the ICD–8 criteria, 74% of the mothers were paranoid schizophrenics.

The mean age at first admission to hospital for the 108 DSM–III-positive mothers was 31.4 years (s.d. 7.6), which was, not unexpectedly, earlier than for the 21 DSM–III-negative mothers (mean 39.8, s.d. 8.5) ($t(127)=4.5$, $P=0.001$). Similarly, the mean age at first admission to hospital for all ICD–8 non-paranoid schizophrenic mothers (simplex, hebephrenic, and catatonic) was 23.3 years (s.d. 4.04) which, again as would be expected, is very much lower than that for paranoid schizophrenic mothers (mean 34.4, s.d. 7.9).

Table II shows the relationship between maternal DSM–III diagnosis (positive/negative for schizophrenia) and diagnosis, grouped as described above, among the 175 offspring. The offspring of mothers diagnosed as schizophrenic according to DSM–III criteria were not themselves significantly more often diagnosed as schizophrenic (9%) than were the offspring of mothers not so diagnosed (4%) (Fishers Exact Probability = 0.70). This lack of significance may, however, be the result of the small numbers involved. The proportion of individuals free from mental illness among the offspring of the DSM–III-positive mothers (28%) is significantly lower than that among the offspring of DSM–III-negative mothers (54%) (Fisher's Exact Probability = 0.02).

Table III shows the distribution of offspring diagnoses as a function of maternal ICD–8 diagnosis. The offspring of non-paranoid schizophrenic mothers (i.e., simplex, hebephrenic, and catatonic) had the highest rate of schizophrenia (29%) and borderline schizophrenia (21%);

TABLE III
Maternal ICD–8 diagnosis by offspring diagnosis

Offspring diagnosis (grouped)	*Maternal ICD–8 diagnosis (grouped)*								
	Schiz. paranoid		*Schiz. non-paranoid*		*Schizo-affective*		*Other*		*Total*
	n	*%*	*n*	*%*	*n*	*%*	*n*	*%*	
Schizophrenic	6	5	8	29	1	8	0	0	15
Borderline	20	16	6	21	2	17	1	13	29
Other	60	47	9	32	4	33	3	37	76
Not ill	41	32	5	18	5	42	4	50	55

that is, 50% of all of these offspring were diagnosed within what may be called a 'schizophrenia spectrum' (Kety *et al*, 1978). Only 18% were free of mental illness. A much smaller proportion of the offspring of paranoid mothers were schizophrenic (5%). This number is significantly less than the corresponding rate among the offspring of non-paranoid schizophrenic mothers (Fisher's Exact Probability < 0.001).

There was no detectable tendency for the ICD–8 subtypes to 'breed true' between mothers and offspring. Of the 13 diagnostically interviewed schizophrenic offspring, only four were paranoid schizophrenics, and of these only one had a paranoid schizophrenic mother, compared with three among the remaining nine non-paranoid schizophrenic offspring (Fisher's Exact Probability = 1.00).

As mentioned above, maternal diagnosis is strongly related to age at first admission to hospital. We have previously shown early age of maternal admission to hospital to be predictive of poorer diagnostic outcome in offspring (Parnas *et al*, 1985). In order to explore the independence of the contributions of diagnostic subtype and age at admission to hospital, we have conducted a series of logistic regression analyses (Fleiss *et al*, 1986) employing diagnostic outcome in the offspring as a dependent variable, and maternal age at first admission to hospital and maternal diagnostic subtype (paranoid *v*. non-paranoid) as independent variables.

In the first analysis the offspring diagnoses were dichotomously grouped into schizophrenic plus borderline ($n = 44$) and other diagnoses ($n = 131$). In this analysis, both maternal age at first admission to hospital and maternal diagnosis subtype have significant chi-squared to-enter values ($\chi^2 = 6.77$, $P = 0.009$, and $\chi^2 = 10.13$, $P = 0.002$). Following forced entry, however, neither variable remained significant after the prior entry of the other. This indicates that the contributions of the variables are not statistically independent of each other.

In a second analysis we compared the contribution of the same two maternal independent variables with offspring diagnoses within the 'schizophrenia spectrum', by comparing the 15 schizophrenic offspring with the 29 borderline schizophrenic offspring. In this comparison neither predictor was significant.

Discussion

In the present study the rediagnoses of the mothers are based on hospital records; i.e. on information collected for clinical rather than research purposes. Hospital records are usually less structured and less comprehensive than information gathered for psychopathological research purposes. In fact, it is not infrequent that clinical information, including discharge diagnosis, is based on the immediate presenting picture at admission, rather than a thorough and comprehensive evaluation of the psychopathology (Parnas & Teasdale, 1987). This might call into question the reliability of the rediagnoses presented here.

Counter to these considerations, however, in 1962 the sample of 129 mothers was selected precisely because their hospital records contained sufficient information to confidently diagnose schizophrenia according to a rather narrow concept of the disease, with emphasis on chronicity. In addition, from 1962 to 1975 the great majority of mothers had several further admissions, often for long periods of time and to different psychiatric departments, yielding a fuller psychopathological picture.

For the diagnosis of schizophrenia, DSM–III requires that the patient's age at onset should be less than 45 years and that the duration of the illness should be more than six months. Estimation of disease onset and duration is necessarily made retrospectively. In the present study, however, no seriously problematic cases were encountered. The very large majority of the mothers were admitted to hospital with a schizophrenic breakdown before the age of 45, and the disease had a chronic course. In view of the potential diagnostic difficulties to be encountered by longitudinal high-risk studies (Strauss, 1984), it is reassuring to find that so high a proportion of the mothers meet the DSM–III criteria now widely used for research. Indeed, among the 21 who did not do so, ten fell only on the criterion of latest age of onset (i.e. 45 years). In the proposed revision of DSM–III, this limit has been raised to 50 years, which would have included nine of these ten mothers. The high level of agreement between the diagnoses made 24 years ago and the present-day DSM–III diagnoses is probably to be attributed to the joint emphasis placed by both diagnostic procedures on both psychopathological and social functioning criteria.

Epidemiological evidence suggests that paranoid schizophrenia is less common than non-paranoid forms (Fuller Torrey, 1981). There may be two reasons why, in the present study, almost three-quarters of the mothers were of the paranoid subtype. Firstly, perhaps because of the later age of onset, the reproductive capacity of this subtype is higher than for all other subtypes, except the schizoaffective (Reisby, 1967; Larson & Nyman, 1973; Erlenmeyer-Kimling, 1978). Consequently, in a sample of schizophrenics selected as being mothers, the paranoid subtype would be particularly well represented. Secondly, the diagnosis of schizophrenia based on hospital records might favour the selection of patients with reliably identifiable productive paranoid symptoms.

Our difficulty in distinguishing the relative influences on offspring outcome of maternal schizophrenia subtype and age at onset arises from the well-established strong association between these two. It is conceivable that the disintegration and disruption of psychic structures seen in non-paranoid schizophrenics (Meissner, 1981) arise precisely because the schizophrenic process afflicts the individual early in his or her life.

The disparity in the prevalence of schizophrenia among the offspring of non-paranoid early-onset mothers versus late-onset paranoid mothers – 29% versus 5% – is surprisingly high compared with that reported elsewhere (Kendler & Davis, 1981). The offspring were diagnosed at a mean age of 24 years, which is rather early in the risk period for schizophrenia, and further schizophrenic cases are to be expected. However, it seems unlikely that such a disparity will be evened out, given that the overall morbidity risk for schizophrenia in the offspring of a schizophrenic parent is estimated to be 10–15% (Gottesman & Shields, 1982).

Based upon earlier findings from our study, we suggest that the disparity could be due to: (a) a greater specific genetic loading for schizophrenia in the offspring of early-onset non-paranoid mothers (Parnas *et al*, 1985), further compounded by assortative mating with schizotypal fathers (Parnas, 1985), and (b) both non-specific genetic and environmental factors effecting the penetrance of the specific genetic loading; for example, birth complications (Parnas *et al*, 1982), early rearing experiences (Parnas *et al*, 1985), and other maternal personality and social characteristics (Talovic *et al*, 1980).

Familial homotypy for schizophrenia subtype has been found by Kallmann (1938), Ödegaard (1963), Farmer *et al* (1983), and Scharfetter & Nüsperli (1980), although not by Tsuang *et al* (1980). Irrespective of how many more schizophrenia cases ultimately manifest themselves in our study in future follow-ups, we anticipate that some degree of homotypy will emerge and that those with paranoid schizophrenic mothers will themselves principally develop paranoid schizophrenia.

A Long-term Follow-up Study of Schizophrenia in Japan – with Special Reference to the Course of Social Adjustment

KAZUO OGAWA, MAHITO MIYA, AKIO WATARAI,
MASAO NAKAZAWA, SHUICHI YUASA and HIROSHI UTENA

A 21–27-year follow-up was conducted on 140 schizophrenic patients consecutively discharged from the Department of Neuropsychiatry, Gunma University Hospital, between 1958 and 1962, and 130 patients (93%) were successfully evaluated. Of these patients, 105 were still living, and the longitudinal courses could be fully observed in 98. With regard to the social outcome of the 105 patients, 47% were assessed as 'self-supportive' whereas 31% were 'hospitalised'. As for psychopathological outcome, 31% were 'recovered', 46% were 'improved', and 23% were 'unimproved'. In the studies of the longitudinal courses of the 98 patients, fluctuating courses of social adjustment were the most numerous in the early stages, whereas in the later stages many of the patients showed differentiation in one of two directions, namely the 'stable self-supportive' state and the 'chronic institutionalised' state. However, this form of differentiation was not revealed in the distribution of psychopathological 'end states'.

This paper reports a longitudinal study of schizophrenic patients which was conducted over a period exceeding 20 years.

In 1958, a five-year project aimed at preventing the relapse of schizophrenic patients was initiated at the Department of Neuropsychiatry, Gunma University Hospital, Japan by the professor at that time, H. Utena. The subjects were 140 schizophrenic patients consecutively discharged from the hospital between 1958 and 1962. The purpose of the project was to clarify prospectively the degree to which relapse could be prevented by placing the patients under what were then the latest therapies, such as neuroleptic drugs, the open-door system, and intensive aftercare. The results of the project, which was carried out until 1967, were reported by Eguma (1962), Utena (1965), and Yuasa *et al* (1969). These reports revealed that the social adjustment of the subjects had clearly been improved. However, as far as relapse was concerned, the results were found to be rather unfavourable. During the period of the project, the guiding principle of rehabilitational activity known in Japan as *Seikatsu-rinsho* was formulated by Eguma, Yuasa and others (Katoh *et al*, 1966; Tajima *et al*, 1967). Literally, this means 'clinical work in a patient's everyday life', but the term 'living skills development procedure' seems to express the meaning more accurately, and it seems to correspond roughly to a combination of individual counselling and social casework in Western methods of management.

The subjects of the project were subsequently followed up and their courses and social outcomes over a period of 16–22 years were reported by Miya *et al* (1984).

The present paper deals with the long-term courses and social and psychopathological outcomes of the same subjects over a period of 21–27 years.

Method

Subjects

The subjects were 140 schizophrenic patients (67 males, 73 females) consecutively discharged from the Department of Neuropsychiatry, Gunma University Hospital, between 1958 and 1962.

Classifying the subjects at the present time according to the ICD-9 (World Health Organisation, 1978), 84 cases are 295.1 (hebephrenic type), 20 are 295.2 (catatonic type), and 36 are 295.3 (paranoid type). As revealed above, the original selection of the subjects at the time of discharge was based on the narrower concept of schizophrenia.

Of the 140 subjects, 81% were under 30 years old, 79% were first admissions, 91% were prescribed neuroleptic drugs during the period of index admission, 87% had terms of index admission of less than six months, and 82% were 'recovered' or 'improved' at the time of leaving the hospital. Also, almost all the subjects were living in or close to a provincial city, Maebashi, about 100 km north-west of Tokyo. Almost all belonged to the middle social class. Population mobility during the follow-up period was not remarkable.

TABLE I
Eguma's Social Adjustment Scale (ESAS)

Self-supportive
1. Has returned to a level of social functioning similar to that prior to onset of illness
2. Maintains an independent social life with or without asking any advice from psychiatrists or acquaintances
3. Maintains a normal family life (housewife, for example)

Semi-self-supportive
1. Displays vocational ability, with some occasional failures
2. Maintains a positive attitude towards work, but needs supervision and guidance
3. Maintains a normal life at home, but hesitates to return to the job held prior to onset of illness

Socially adjusted to family or community
1. Works when encouraged with continuous significant support from others
2. Needs more time before being ready to return to previously held job
3. Able to work continuously if the work is kept at a simple level

Maladjusted
Social adjustment not possible
1. Non-productive life (able to be cared for at home)
2. Anti-social (admission to psychiatric hospital necessary)

Hospitalised
In psychiatric hospital

Assessment

The investigation of the course and outcome of the subjects was concentrated mainly on the aspect of social adjustment in the same way as previous reports on the same subjects. However, this investigation also covered the aspect of psychopathology.

For the assessment of social adjustment, we used Eguma's Social Adjustment Scale ESAS; (Eguma, 1962) (Table I), which we had used in previous studies. We assessed the course of social adjustment of each case, month by month, throughout the whole term.

For the psychopathological assessment of the outcome, we used the criteria of 'recovered', 'improved' and 'unimproved' which had been used in assessing the outcome at the time of the patients' leaving hospital. For the psychopathological assessment of the course, especially in the last five years, we used the category of 'end state' (Bleuler, 1972). In the criteria mentioned above, 'recovered' means a state without positive schizophrenic symptoms, 'unimproved' refers to a state with remarkable positive and/or negative symptoms, and 'improved' means a state with mild positive and/or negative symptoms.

Information was collected in the following ways. We used data which had already been accumulated in previous studies; the results of analysis of clinical charts and nurses' records from the medical institutions involved; information from doctors, nurses, public health nurses working in the community, and caseworkers; interviews with patients' families, relatives, and acquaintances; and data provided by administrative agencies. Also, interviews were held with as many patients as possible (80%).

Our last follow-up in this study covered the period up to the end of January 1984.

Results

The follow-up was completed in 130 (93%) of the 140 patients (62 males, 68 females). Of the 130 patients, 105 (48 males, 57 females) were still living at the time of the study, and in 98 of these (45 males, 53 females), longitudinal courses were fully observed.

The observation period for the 105 living patients was in the range 21.1–27.2 years, the average being 23.6 years (the duration of illness was 21.3–47.0 years, the average being 26.4 years). The mean age of the patients was 48 years (range 36–70 years) at the end of the follow-up period.

Twenty-five patients (14 males, 11 females) had died during the follow-up period. Suicides accounted for more than half of the deaths (14 patients). Of the other deceased patients, six had died suddenly of unknown cause, one had died of acute cor pulmonale, one of general prostration, one of asphyxia, and we were unable to obtain information concerning the cause of death of the remaining two.

The following results are limited to the living subjects only.

Outcome

Social outcome

The social outcome at the end of the follow-up period, as assessed on ESAS, is shown in Table II. The outcome was regarded as favourable in 'self-supportive' cases, which constituted 47% of the 105 living subjects, and unfavourable in 'hospitalised' and 'maladjusted' cases, which totalled 34%. The cases in the middle grades of ESAS, namely 'semi-self-supportive' and 'socially adjusted to family or community', amounted to only 19%. It was found that many of the cases had become polarised into 'self-supportive' and 'hospitalised'.

TABLE II
Social outcome

Social adjustment	*Male*	*Female*	*Total (%)*
Self-supportive	24	25	49 (47)
Semi-self-supportive	4	4	8 (8)
Socially adjusted to family or community	5	7	12 (11)
Maladjusted	0	3	3 (3)
Hospitalised	15	18	33 (31)
Total	48	57	105 (100)

When the above outcome was substantiated from the aspects of occupational, marital, and residential status, the results were as follows. As to occupational status, 78 (74%) of the 105 patients were fully productive or productive to some extent. Of these 78 patients, 49 were 'self-supportive', 20 were outside a hospital although not 'self-supportive', and 9 were still 'hospitalised', in the sense that they were attending on a 'night-hospital' basis. Such 'hospitalised' patients accounted for 27% of all 'hospitalised' subjects. This was because of the difficulty in discharging these patients, who were not acceptable to their families or to alternative accommodations, of which there are few in the part of the country covered by the study.

As to marital status, of the 105 patients, 47 (45%) were married, 11 (10%) were divorced and 47 (45%) were unmarried. Among the 'self-supportive' cases, 82% were married; among the 'semi-self-supportive' and 'socially adjusted to family or community' cases, 15% were married; and among the 'maladjusted' and 'hospitalised' cases, only 8% were married.

As to residential status, of the 105 patients, 52 (50%) were living in their own homes, 20 (19%) were with parents or other relatives, and 33 (31%) were in psychiatric hospitals. Among the 'self-supportive' cases, 96% were living in their own homes, while among the 'semi-self-supportive', 'socially adjusted to family or community', and 'maladjusted' cases, only 22% were living in their own homes.

Psychopathological outcome

The psychopathological outcome at the end of the follow-up period is shown in Table III according to the criteria mentioned above. There were 31% 'recovered', 46% 'improved', and 23% 'unimproved'. The number of middle-grade cases was the greatest, and the polarisation to two extremes as observed in the social outcome was not seen here.

TABLE III
Psychopathological outcome

Psychiatric state	*Male*	*Female*	*Total (%)*
Recovered	19	14	33 (31)
Improved	23	25	48 (46)
Unimproved	6	18	24 (23)
Total	48	57	105 (100)

Table IV shows the correlation of the psychopathological outcome with the social outcome. It can be seen that the 'improved' patients showed degrees of social adjustment ranging from 'self-supportive' to 'hospitalised', and that they accounted for one-third of the 'self-supportive' and one third of the 'hospitalised' patients.

Treatment

Of the patients alive at the end of the follow-up period, 69 patients (66%) were under psychiatric care. This high percentage may be due to the fact that there were many patients in whom relapse had occurred, resulting in resumed, and subsequently prolonged, treatment; 78% of patients had been readmitted one or more times. Almost all the patients (96%) under psychiatric care were taking neuroleptic drugs.

Even among the 49 'self-supportive' cases, 20 (41%) were under psychiatric care. Many of these cases had mild psychiatric symptoms. Of the 'semi-self-supportive', 'socially adjusted to family or community', and 'maladjusted' cases (23 in all), 16 (70%) were under psychiatric care, and 7 had dropped out of psychiatric care.

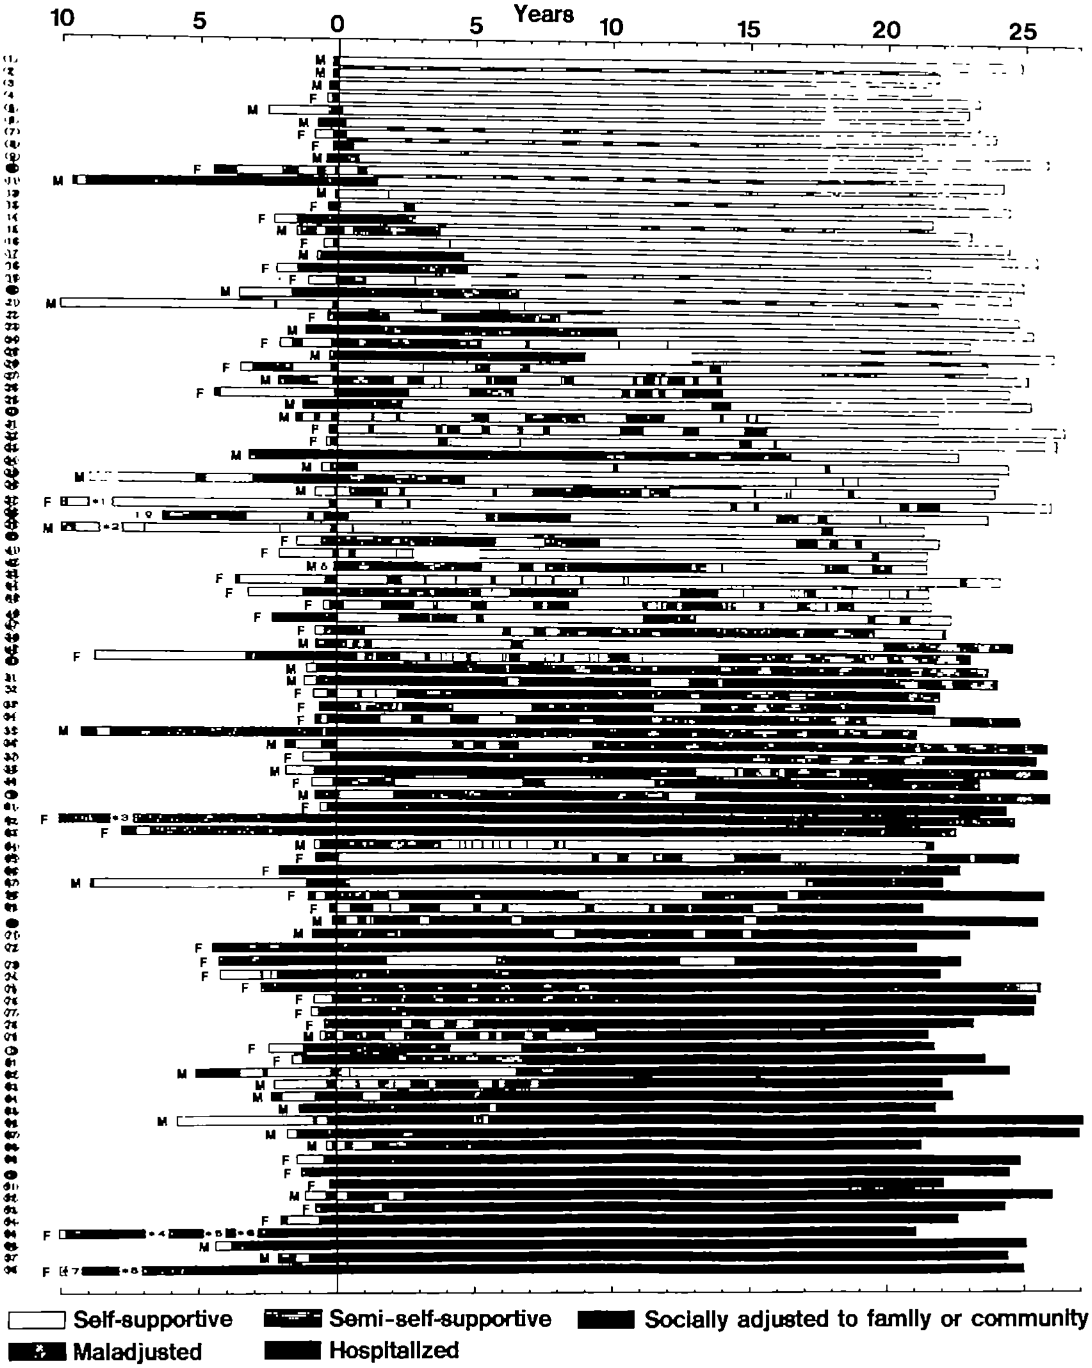
Course

Course of social adjustment

In 98 patients, the longitudinal courses were assessed and illustrated month by month using the five ESAS grades, as shown in Fig. 1, in which the passage of time is plotted

TABLE IV
Correlation between psychopathological outcome and social outcome

Social adjustment	*Psychiatric state*			*Total*
	Recovered	*Improved*	*Unimproved*	
Self-supportive	33	16	0	49
Semi-self-supportive	0	8	0	8
Socially adjusted to family or community	0	11	1	12
Maladjusted	0	2	1	3
Hospitalised	0	11	22	33
Total	33	48	24	105



*1-8: Abbreviations

FIG. 1 The course of social adjustment.

TABLE V
Correlation between 'end states' and social course types

	Stable self-supportive		*Fluctuating and stable middle*		*Chronic institutionalised*		*Total*	
Subjects	35		32		31		98	
'End states': number of subjects	33	(94%)	9	(28%)	29	(94%)	71	(72%)
Recovery	23		0		0		23	
Mild chronic	10		4		4		18	
Moderately severe chronic	0		5		13		18	
Severe chronic	0		0		12		12	

horizontally, and the origin point is the start of follow-up. The illustrated courses for each patient were arranged in order from good to bad in terms of social adjustment as follows:

(a) 'Stable self-supportive' patients, who were in a long-term 'self-supportive' state for at least 5 years immediately prior to the end of the follow-up period, were arranged from the top in the order in which they reached this state.

(b) 'Chronic institutionalised' patients, who were in a long-term 'hospitalised' or 'maladjusted' state for at least 5 years immediately prior to the end of the follow-up period, were arranged from the bottom in a similar manner.

(c) The remaining patients were arranged below the category of 'stable self-supportive' in order from good to bad in terms of the social adjustment outcome at end of the follow-up period.

In Fig. 1, it can be seen that in the early stages of the long-term course, fluctuating courses were the most numerous, while in the later stages these courses gradually decreased in number and many of them differentiated in one of two directions, namely to the 'stable self-supportive' state and to the 'chronic institutionalised' state; out of the 98 patients, there were 35 of the former and 31 of the latter. The remaining 32 patients were termed 'fluctuating and stable middle' types; 25 of these were 'fluctuating' patients and 7 were 'stable middle' patients, who were in either of two long-term middle states in the ESAS for at least 5 years immediately prior to the end of the follow-up period.

Fig. 1 shows that the two curves obtained by plotting the initial points at which individual patients attained 'stable self-supportive' states and 'chronic institutionalised' states, respectively, were smooth and unbroken and in addition formed a symmetrical pattern.

This phenomenon was found to be the same even if the origin of the time plot in Fig. 1 was changed to the time of onset of illness or to the time of first admission. Therefore we called this phenomenon, in which fluctuating courses gradually decreased in number, and many differentiated in one or the other of two directions, 'the scissors phenomenon', as it resembled a pair of scissors with the blades open and facing in two directions.

Psychopathological course, especially 'end state'

For the psychopathological assessment of the course, especially the last 5 years, we used the category of 'end state' (Bleuler, 1972). Table V shows the result, and its correlation with the course of social adjustment. It can be seen that the proportion of patients who attained an 'end state' amounted to 72% (71 of 98). This proportion coincides closely with that (74%) of patients in a socially stable state (the 'stable self-supportive' state, the 'chronic institutionalised' state, or the 'stable middle' state).

As to the proportion of patients who attained an 'end state' in each social course classification, this amounted to 94% among the 'stable self-supportive' patients; and among the 'chronic institutionalised' patients, the same high proportion was observed. Among the 'fluctuating and stable middle' patients, nine (28%) attained an 'end state'. Seven of these nine were 'stable middle' patients, and only two had a fluctuating social course.

From these results, it was found that there is a close correlation between the 'end state' and the socially stable state.

The 'end states' were distributed as follows. In the 'stable self-supportive' type, most patients (70%) had recovered, and mild chronic 'end states' also occurred (30%). In the 'chronic institutionalised' type, 41% were severe chronic 'end states', but more (45%) were moderately severe chronic 'end states', and mild chronic 'end states' also occurred (14%). Overall figures were: recovery 32%, mild chronic 'end states' 25%, moderately severe chronic 'end states' 25%, and severe chronic 'end states' 17%. In the distribution of 'end states', the differentiation in two directions which was found in social adjustment did not occur.

Discussion

Our results on the outcome for schizophrenic patients showed that 47% were 'self-supportive' with regard to social adjustment, whereas 31% were 'recovered' with regard to psychopathological outcome. Of the 'self-supportive' patients, all were fully productive, almost all (96%) were living in their own homes, and the majority (82%) were married. But even among the 'self-supportive', 41% of the patients were under psychiatric care.

The results of earlier studies on the long-term outcome of schizophrenia in Japan indicated that drug therapy had no effect on the percentage of patients who recovered completely, although it

TABLE VI
Proportion and distribution of 'end states'

	Bleuler (1972)	*Ciompi & Müller (1976)*	*Huber* et al *(1979)*	*Present report*
Average follow-up term: years	22	36.9	22.4	23.6
Subjects	208	289	502	98
'End states': number of subjects	152 (73%)	262 (91%)	367 (73%)	71 (72%)
Recovery: percentage of end states	20	29	26	32

Moderately severe chronic: percentage of end states	24	26	29	25
Severe chronic: percentage of end states	24	20	14	17

reduced the number of patients with severe defects and increased the number with slight or moderate defects (Gotoh, 1971; Murakami, 1971; Shimazono, 1974; Aritome, 1978). However, as to the social outcome, a trend towards improvement in outcome has been noted; that is, the percentage of 'self-supportive' cases has increased as a result of intensive aftercare, including drug therapy (Yuasa, 1984). These findings are confirmed by results of our present study, which is a longer follow-up study than those mentioned above.

In other countries, several reports of follow-up studies of schizophrenia exceeding 20 years were published in the 1970s (Bleuler, 1972; Ciompi & Müller, 1976; Huber *et al*, 1979; Tsuang *et al*, 1979). Although it is difficult to make an exact comparison between these studies and our own, we have tried to do so on a limited basis, especially with regard to the percentages of cases in the 'self-supportive' state and those that recovered completely.

Bleuler (1972) performed a very careful follow-up study of 208 schizophrenics for more than 20 years and, according to his results, a social outcome of 'employable, outside a clinic', which seems equivalent to a status of 'self-supportive' in our study, accounted for 34% of the probands. This proportion was greater than the proportion (22%) of complete recoveries (the "undulating courses types progressing to recovery"). Studies by Huber *et al* (1979, 1980) and Tsuang *et al* (1979) produced similar results to those of Bleuler; in the study of Huber *et al*, the 'social remission degree 0' cases accounted for 39%, while the proportion of complete remissions was 22%; in the study of Tsuang *et al*, those having a rating of 'good' in 'occupational status' made up 35%, while 'good' patients with regard to 'psychiatric symptoms' accounted for 20%. The results of the study by Ciompi & Müller (1976, 1980) differed from these results in that only 15% of patients were 'good' in 'social adaptation', while 20% achieved 'total remission'. This seems to have been chiefly due to the advanced age of the probands (the average age was 74 years at follow-up). The above results from three studies, except those of Ciompi & Müller, are in agreement with our results in that the number of cases equivalent to 'self-supportive' was greater than the number of cases that recovered completely. However, in our results the percentage of 'self-supportive' patients is higher than that in the other three studies. This seems to be due to the fact that almost all our subjects had been under intensive aftercare, including neuroleptic medication from the early stages of the illness, whereas in the other three studies there were many subjects treated before the era of drug therapy. In other words, it is thought that neuroleptic medication, when used in conjunction with intensive aftercare, improves the long-term social outcome of patients with schizophrenia.

As to the course of social adjustment, our results showed that various courses were observed, but that overall, the characteristic pattern which we called 'the scissors phenomenon' occurred. The features of 'the scissors phenomenon' are:

(a) Transition from fluctuating courses to stable courses.
(b) Differentiation of the transition in two directions (one to the 'stable self-supportive' state and the other to the 'chronic institutionalised' state).
(c) Smooth, unbroken continuity of the transition.

Although the classification of the course types in schizophrenia has already been reported in many studies (the eight types of Bleuler, the eight types of Ciompi & Müller, and the 12 types of Huber *et al*, etc.), a fine, clear-cut distinction between subtypes was difficult to achieve in the present study.

Table VI shows the results for the 'end state' in the above three studies and our study. It is seen that as to the percentage of patients who attained an 'end state', our results coincide closely with those of Bleuler and of Huber *et al.* However, the percentage reported by Ciompi & Müller is higher than those in the other three studies. This seems to be due to the difference in the length of the follow-up term: the percentage of patients attaining an 'end state' seems to become higher when the course of the illness is longer and the age of each patient is higher. However, the difference in the length of the follow-up term does not influence the distribution of 'end states'. In particular, the results of all four studies are consistent in that the percentage of the middle grades (mild chronic and moderately severe chronic) of 'end state' is 50–60%. This differs remarkably from the distribution of socially stable states, in which differentiation in two directions was observed in the course of social adjustment.

We shall now deal with the relationship between 'the scissors phenomenon' and each course. It is necessary to pay attention to the fact that the cases in the 'stable self-supportive' state and in the 'chronic institutionalised' state, which increase in number gradually in the later stages of the course, change places to some extent with the cases in the 'fluctuating and stable middle' states. Although the 'stable self-supportive' and 'chronic institutionalised' states are not easy to change, they are not altogether unchangeable. For instance, in the last 5 years of the course, 6 (9%) of 64 patients in the 'stable self-supportive' and 'chronic institutionalised' states changed to the 'fluctuating and stable middle' states. However, in the same period, 12 (32%) of 38 patients in the 'fluctuating and stable middle' states changed to the 'stable self-supportive' or 'chronic institutionalised' state. Consequently, the number of cases in the 'stable self-supportive' and 'chronic institutionalised' states increases and 'the scissors phenomenon' progresses.

The present report deals with the course and outcome of schizophrenia as a whole. We are now analysing the other important issues involved in the prognosis of schizophrenia.

Conclusions

In the era of use of neuroleptic drugs, a trend towards improvement in the social outcome of schizophrenia has been recorded. This seems to be due to the effect of intensive aftercare, including neuroleptic medication from the early stages of the illness.

The percentage of complete recoveries with regard to psychopathological outcome seems to have remained at a similar level to that existing before the era of use of neuroleptic drugs. This shows the limit of these treatments. Furthermore, the percentage of cases with a favourable outcome without need of care still remains at a low level, and the length of the term spent under care tends to have been increased. These problems remain to be solved.

During the course of social adjustment, fluctuating courses in the early stages change on the whole to stable courses in the later stages. This is correlated with the increase in the number of patients who attain an 'end state' in the later stages.

The differentiation in two directions observed in the course of social adjustment is not seen in the distribution of 'end states' in psychopathology. This is characteristic of the course of social adjustment.

As to the 'chronic institutionalised' state, which is one of the two directions taken, this has again been brought to the fore as a problem to be solved, especially for those patients who remain in a psychiatric hospital even though their psychiatric condition is not very serious, making it apparent that social support systems should be established immediately in Japan.

Mode of Inheritance as Indicated by One-sided and Two-sided Familial Taint: With an Application to Schizophrenia

ERIK ESSEN-MÖLLER and JAN LANKE

Among his various approaches to an understanding of schizophrenic inheritance, whether dominant or recessive, Rüdin (1916) also compared the respective frequencies of one-sided and two-sided familial taint. Essen-Möller (1949) tried the idea on another sample, but neither of us arrived at a definite choice. Later on Slater (1966) surprisingly demonstrated that unilaterality is typical not only of dominant but also of polygenic transmission. In the present paper we adjust Slater's computation and, in so doing, accentuate his result. We also find a similar preponderance of unilaterality on a recessive model, and offer an explanation for this. The findings substantially reduce the efficacy of laterality of taint as an indicator of mode of inheritance.

In a way this paper had its origin more than 40 years ago, when the families of 73 schizophrenic patients (see Appendix 1) were investigated by the first author (EEM) (who is sole author of this historical section). The purpose was to contribute to the contemporary discussion of whether schizophrenia, seen as a homogeneous genetic disease, was inherited according to a dominant or a recessive model.

The method consisted in studying the distribution of one-sided and two-sided familial taint. With dominant transmission, the illness was expected to occur, in most cases, on just one of the two ancestral sides; that is, either on the maternal or on the paternal side but not on both. Recessivity would imply more cases where the illness occurred on both ancestral sides.

The first to apply this line of thought was probably Rüdin (1916), in his classical work on the genetics of dementia praecox. Actually he found a moderate preponderance of unilaterality, but less so when a wider definition of the illness was applied. The preponderance was thought to be possibly due to incompleteness of his sample (which may not have been collected primarily with the problem of laterality in mind). So with due reservation Rüdin was inclined to assume recessivity, an opinion supported by conventional studies irrespective of side (Lundborg, 1913; Rüdin, 1916).

Some 25 years later the perspective had changed, and for various reasons it had become natural for me (EEM) to believe chiefly in dominant transmission.

For one thing, the concept of reduced penetrance had made the exact proportions within separate types of relatives less informative, and had shifted the interest to a comparison between the types. Now the children of schizophrenics were found to run approximately the same risk as did the sibs, a finding in favour of dominance (Lenz, 1921, 1937). Secondly, the exceptionally low incidence in parents of schizophrenics, for a long time a major argument for recessivity (Luxenburger, 1937, 1939), could now be explained as resulting from a reduced marriage rate in affected individuals, and such reduction was shown to occur even premorbidly (Essen-Möller, 1935, 1936; Lenz, 1937). Thirdly, it was recognised that the pattern according to which affected children of schizophrenics were scattered over families would require, on a recessive model, a much higher frequency of gene carriers among the probands' mates than was reasonable or could be verified by any substantial increase of taint in the families of mates (Schulz, 1938; Leistenschneider, 1938; Koller, 1939; Egger, 1942; Früh, 1943).

Accordingly, it was a surprise to me when my own sample, which had been collected expressly for a study of laterality, appeared to present a bilateral distribution and thus to suggest recessivity. I doubted my method of calculation, and after some time submitted the problem to an international congress of geneticists, asking for suggestions and advice (Essen-Möller, 1949). Eliot Slater, who was present, agreed that the method was probably too primitive for the purpose. Much like Rüdin, I had simply compared the morbidity in relatives of non-psychotic parents according to whether or not the other parent was psychotic. However, no better method was suggested, the problem remained unsolved, and my sample was laid to one side (although used in other connections).

The next opening came when a third model, the polygenic, caught interest within medical genetics.

To be sure, this model had already become accepted for certain normal traits with a quantitative variation, like stature and intelligence. The gradation of such traits from slight to pronounced was assumed to depend not on which particular polygenes were present, but rather how many. Depending on their contents of relevant polygenes, 'the genetic liability', the separate individuals were conceived to be distributed symmetrically around the population mean according to the well-known normal or Gaussian curve. In relatives pertaining to a defined proband, the liabilities would likewise be distributed normally, but their mean would be dislocated toward the proband in proportion to the degree of relationship.

Now several authors (e.g. Carter, 1958; Edwards, 1960; Crittenden, 1961; Falconer, 1965; Gottesman & Shields, 1967) suggested that qualitative and abnormal traits too, such as diabetes or schizophrenia, might be interpreted as polygenic provided there was a threshold, a critical number of abnormal polygenes, that had to be exceeded for the trait to have a chance of showing up, other conditions ('penetrance') permitting. Because of their dislocated distribution, the relatives of probands would surpass the threshold and get affected more frequently than do random individuals.

Although the polygenic threshold model might represent an adequate solution to various intricate problems, doubts were put forward regarding its generality (Morton, 1967), and specifically its application to schizophrenia (Shields & Slater, 1967; Dalén 1972; Essen-Möller, 1977, 1979). Thus even the polygenic model proved difficult to distinguish from dominance by means of conventional methods. So far the situation was reminiscent of the time when the alternative to dominance was recessivity. As once Rüdin (1916), so now Slater (1966) had the idea of probing whether a study of laterality of taint might help to elucidate the problem. To this end he developed a sophisticated procedure of his own, and subsequently quite a number of psychiatrists applied his results to their samples of functional disorder (Slater & Tsuang, 1968; Perris, 1971; Tsuang, 1971; Slater *et al*, 1971; McCabe *et al*, 1972; Mendlewicz *et al*, 1973; James & Chapman, 1975; Johnson & Leeman, 1978; Pauls *et al*, 1979; Baron, 1980; Rinieris *et al*, 1981). So I could not resist taking up the topic once more and reviving my hibernated sample.

To that end I associated with Jan Lanke, mathematician–statistician. He suggested a number of adjustments and improvements on Slater's strategy, and will give an expert presentation elsewhere; he also planned and carried through the extensive computations required for the data analysis.

Fortunately we had notified Eliot Slater about our project in the year prior to his death, and had his agreement in principle in two most encouraging and amiable letters. The preceding notes largely comply with his wish for a presentation of "the true history of the idea".

Theoretical considerations

Slater's strategy for predicting laterality of taint on a polygenic threshold model

Clearly there is a difficulty in analysing simultaneously both ancestral sides of all families in an entire sample of probands. This is so because of the varying number of relatives on either side and the varying number of affected individuals among them. At this point Slater had the idea of confining his computations to families with two affected relatives on the two sides taken together. When more than two affected individuals were present, he regrouped them into sets of two, in every possible combination, and subsequently compensated for the excess weight that this policy entailed in such families (Slater & Tsuang, 1968).

By this arrangement the number of affected individuals on either side could be only zero, one, or two. Out of the resulting nine combinations, only three would add up to the stipulated number of two affected relatives on the two sides taken together; namely, (a) no maternal and two paternal; (b) one on each side; (c) two maternal and no paternal. The first and the third of these three crucial combinations are seen to represent unilaterality, and the second, bilaterality.

Admittedly this formulation of the problem reduced substantially the number of families available for calculation. In exchange, it implied a striking simplification as compared with earlier attempts, where families with a single affected relative were also included.

With these ideas in mind, Slater started out by combining two Gaussian distributions, which were taken to represent the two sexes of an unselected population mating at random. This combined distribution is again of the Gaussian type, to be visualised now as a symmetrical hill. The pairs of mates were grouped together into numerous classes or cells, corresponding to the deviations of the two mates from their population means in units of standard deviations. The expected frequency (probability) of any cell is the product of the probabilities of the mates.

The mid-parent value of each pair of mates is also, according to the rules of population genetics, the mean liability of the children of those mates, or parents. The probability of such a child being affected is obtained as that proportion of the children's distribution which transgressed the threshold.

The three probabilities – one for each parent, one for the child – were multiplied together, and their product was stored.

Slater then proceeded, within every cell, from the mothers of affected children to the mothers' sibs, that is, to the maternal uncles and aunts of the affected children, which were now posited as fictitious probands. The distribution of these maternal uncles and aunts around their dislocated mean was computed, and so was the probability of their containing among themselves either none, one, or two affected individuals. The same procedure was accomplished on the paternal side.

Finally the probability for each one of the three crucial constellations of affected uncles and aunts pertaining to each cell (0+2), (1+1), (2+0) was weighted (multiplied) by the stored probability of the cell, and the products for all cells were then summed. The three resulting sums would constitute, according to Slater, the three requested odds (or probabilities) for uni- and bilaterality of the affected uncles and aunts on a polygenic threshold model.

Adjustments of Slater's procedure

Summation over cells. The summation over cells, described at the end of the previous section, was somewhat invalidated by a slip. From each of the three terms presented by Slater (1966, p. 160), a constant factor $n(1-p)^{n-2}(1-m)^{n-2}/2$ has been eliminated. When summing over all cells this does not work since the factor removed is different in different cells as soon as there are more than two relatives on each side. The error is easily corrected by not making the cancellation.

Standard deviations. While Slater correctly worked with dislocated means for the relatives of probands, he overlooked the fact that the standard deviation of relatives is smaller than that of the unselected population. In proportion to the degree of relationship (correlation) with the proband, this reduction in standard deviation slightly restricts the risk for a relative to transgress the threshold and get the disease. It is the joint effect of dislocation and reduction in standard deviation that has to be considered.

Dependence between relatives. Slater conceived the nine aforementioned combinations of uncles and aunts as the products of two binomial expansions, one for each side of the family. For instance, in the case of two maternal uncles, he would put the probability for both of them to be ill equal to the square of the probability that relates to just one of them, and correspondingly on the father's side. However, the probability of two ill on the same side is greater than that square, indeed considerably greater. This follows from the correlation which prevails between the relatives. The phenomenon is in principle the same as that referred to by Edwards (1960) when he says that the risk to the unborn increases with the number of relatives ill (cf. Ødegaard 1972; Essen-Möller 1977). Of course the correlation also affects the remaining terms of the presumed binomial expansions. The uncorrected binomials simply do not apply in the situation. For an adequate computation, we built the appropriate correlation into each of the two distributions.

The three adjustments combined. In his polygenic model, Slater posited the threshold at $+2\sigma$. At full penetrance, where phenotype equals genotype, this implies, according to tables of the normal distribution, that 2.28% of the population would be affected. When applied to families with exactly two affected uncles and aunts on the two sides taken together, and (about) ten uncles and aunts overall on each side, Slater computed from these assumptions the odds 4675:4193:4675 for the three crucial constellations of laterality. In small families (two members on each side) the proportion of the bilateral group was doubled. In terms of probabilities of unilaterality this equals 0.6904 in large families and 0.5272 in small ones. Making all three adjustments described above increases these probabilities to 0.7960 and 0.7796, respectively.

Probability of unilaterality on different genetic models

Slater and followers (see Slater & Tsuang, 1968) were prepared to decide in favour of dominance when the observed frequency of unilaterality was significantly higher than the calculated polygenic expectation. Now we supplement this indirect inference by introducing a direct comparison with calculated dominant expectation, and, for completeness, also with recessive expectation, still with 2.28% genotypical population frequency and full penetrance. The resulting probabilities in families of different size are presented in Table I.

As could be foreseen, the dominant model had the highest probabilities of unilaterality, the polygenic the lowest, while recessivity held an intermediate position.

TABLE I

Expected proportion of unilaterality in large and small families on different genetic models (genotypic population frequency 2.28%, penetrance 1.00)

	Polygenic	*Recessive*	*Dominant*
Large family (10+10)	0.7960	0.9820	1.0000
Small family (2+2)	0.7796	0.8156	0.9642

The span between the three models is strikingly narrow, and in view of the sample size required for a significant genetic differentiation, it appears doubtful whether the study of ancestral laterality will prove as helpful as had been hoped.

Unilaterality is seen to predominate throughout the table. It is unequivocally the most probable finding whatever the mode of transmission. This is in striking disagreement with the intuitive concepts with which Rüdin, Essen-Möller, and Slater started their investigations. It is true that certain corrections had to be performed with regard to Slater's computations, but this did not restore the bilateral distribution that Slater had anticipated with polygenic transmission; rather, we ended by supporting and accentuating Slater's discovery that unilaterality is typical not only of dominant but also of polygenic transmission, and we also added a similar finding for recessivity.

Obviously there is reason for looking closer into the nature of this apparent mystery. The following theoretical explanation is offered with regard to the recessive model.

Recessive unilaterality explained

The fact that the proband is homozygous implies that the abnormal gene must be present in both parents, and hence in one of the maternal and one of the paternal grandparents as well. Let us denote as 'loaded' the two grandparents that have provided the proband's parents (and subsequently the proband) with the gene in question; the two remaining grandparents may be characterised as 'free'. From the loaded grandparents the abnormal gene may spread also among the proband's uncles and aunts, and this will largely occur to the same extent on both ancestral sides. This is what might seem at first sight conducive to bilaterality.

However, one single recessive gene does not produce the illness. Should it so happen that the illness is actually displayed in an uncle or aunt of the proband, then a complementary additional gene of the same sort must be present in the free grandparent on the relevant side. This additional gene stems from the population, where it has a certain frequency. If the gene is a rare one, the chances are low that both of the free grandparents possess it, and bilateral illness among uncles and aunts is therefore infrequent. It is much more common that an additional gene occurs in just one or the other of the free grandparents, and this implies a comparatively high frequency of unilaterality among the affected uncles and aunts.

Let us put it this way. The proportion r of abnormal recessive genes among all genes at the same locus is the square root of the frequency r^2 of the homozygotically abnormal individuals in the population; for example, 10% if the population frequency is 1%. The frequency of the carriers of the abnormal gene (whether hetero- or homozygotic) is $2r(1-r)+r^2$; in this example 19%. Accordingly, the probability of the abnormal gene occurring bilaterally, that is in both of the free grandparents, is $0.19^2 = 0.0361$. In contrast, for the abnormal gene to occur unilaterally, that is either on the maternal or the paternal side but not on both, the probability is $2 \times 0.19(1-0.19) = 0.3078$. This means that the odds for unilaterality are about 8½ times those for bilaterality. With a genotypical population frequency of 2.28%, the odds for unilaterality would be about 5:1.

One might venture to speculate that a similar mechanism, if more complicated, is at play in polygenic transmission.

Empirical findings

Observed and expected unilaterality

Having dealt so far with computations in theoretical models, we shall now turn to the actual schizophrenic sample referred to in the historical section and described in Appendix 1.

For every observed family with two or more affected relatives on the two ancestral sides taken together, a hypothetical family with the same number of paternal and maternal members and the same number of affected individuals was constructed. Within this hypothetical family, the expected frequency of unilaterality was computed and compared with observation. The comparison was made both with and without regard to certain background variables of conceivable influence, such as sex, age and length of observation (see Appendix 1), and of course under various assumptions regarding genetic model, genotypic frequency, and degree of penetrance. The comparison was also

TABLE II

Observed laterality by diagnostic classification

Uncles and aunts			*Uncles, aunts and parents*		
Cumulated diagnosis	*Number of unilateral families*	*Total families*	*Cumulated diagnosis*	*Number of unilateral families*	*Total families*
D1	–	–	D1	3	3
D2	2	3	D2	6	8
D3	3	5	D3	9	12
D4	8	12	D4	13	20
D5	10	18	D5	13	25

performed with and without inclusion of the parents. The entire procedure was finally repeated within each of the five extensions of the diagnostic classification, as described in Appendix 1 and Table II. When, for instance, the D5 criteria were used, there are 18 families with two or more affected uncles and aunts and 25 families with two or more affected members including parents. In 10 and 13 of these families, respectively, the affected members are all on one side, and in the remainder they occur on both sides.

The voluminous crosswise tabulations cannot be presented here. A brief exemplification is offered in Tables III and IV. Table III shows, that, for instance, when the D3 diagnosis was applied, there were five families with two or more ill relatives, three of which were affected unilaterally and two bilaterally. The expected number of unilateral families was 3.74. Table IV gives the expected frequencies of unilateral disease (D3) for each of the three genetic models, when the genotypic population frequency is put at 5%, 2.5% and 1% and the penetrance at 0.2, 0.4 and 1.0, respectively.*

The closest *proximity* between observed and expected *frequency* of unilaterality was found, with rare exceptions, on the polygenic model. Recessivity came almost as close, while dominance was slightly more distant. Exclusion or inclusion of other variables, such as parents, age, and length of observation, did not appreciably influence this order of proximity between the models.

---

*The combinations of genotypic population frequency and degree of penetrance were chosen so as to comply approximately with the commonly accepted 1% phenotypic incidence of classical schizophrenia. The combination 2.5% × 0.4 (which is close to Slater's assumption) would also go well with the gap between 25% for the genotypic expectation and 10% for the phenotypic observation in the sibs of schizophrenic probands on a recessive model. Similarly, the combination 5% × 0.2 might exemplify the corresponding gap in the proband sibs under dominant transmission (50% as against 10%).

TABLE III

Frequencies and likelihoods of unilateral and bilateral disease in a diagnostic subsample of five families of varying composition (Diagnosis D3; polygenic model; genotypic frequency 2.5%; penetrance 0.40 (sex, age, length of observation, and parents not considered))

	Number of uncles and aunts			*Unilateral sets of affected individuals*		
Family code	*Paternal*	*Maternal*	*Affected*	*Observed*	*Expected*	*Likelihood*
35	6	3	2	1	0.8114	0.8114
45	5	8	2	0	0.8080	0.1920
46	5	3	2	1	0.7996	0.7996
64	8	8	3[1]	1	0.7050	0.7050
73	8	8	4[1]	0	0.6186	0.3814
				3	3.7426	0.0335

1. Instead of regrouping into sets of two the families with more than two affected relatives, it was here preferred to keep together the total number of affected individuals, and to accept such a family as unilateral only when all of its affected members occurred on the same side. Obviously this method, too, complies with Slater's principle of three crucial and mutually exclusive alternatives. The difference is of no practical avail.

TABLE IV

Expectations of unilaterality and likelihoods of observed lateralities (same diagnostic subsample as in Table III; variable genetic model, genotypic frequency, and degree of penetrance)

	Assumed genotypic frequency and penetrance		
Genetic model	*5%, 0.20*	*2.5%, 0.40*	*1%, 1.00*
	Expected number of unilateral families[1]		
Polygenic	3.35	3.74	4.05
Recessive	3.29	3.81	4.63
Dominant	4.08	4.70	4.99
	Likelihoods		
Polygenic	0.0441	0.0335	0.0227
Recessive	0.0437	0.0305	0.0041
Dominant	0.0223	0.0028	0.0067

1. As against 3 observed.

Likelihoods. The likelihoods, as shown in the last column of Table III and in the bottom part of Table IV, are the cumulated products of such probabilities of uni- and bilaterality as were realised among the families of a subsample. With few exceptions, the maximal likelihoods were found to be associated with the polygenic model, although recessivity gave likelihoods not far from the maximal in most cases. Once again, the background variables influenced the results only marginally.

Conclusion

A high level of unilateral taint prevails among the uncles and aunts of affected probands, and this is typical not only of dominant but also of polygenic and recessive transmission. These results clearly have a bearing beyond the concept of schizophrenia – if the latter can, indeed, be regarded as a genetical unit.

Appendix 1 (EEM)

Psychiatric sample

The sample was drawn from the first admissions through years 1927–1941 to a new mental hospital from a defined rural area of South Sweden. About one fifth of the patients had been transferred from other mental hospitals or had a history of earlier episodes with or without hospital admission. In spring 1942, I (EEM) selected those patients whose record, either original or continued, seemed to justify a diagnosis of classical schizophrenia. In order to facilitate the collection of family data, the last third of the sample was restricted to patients born 1902 or later, and with both parents living at the time of the field work.

The field work took place in the summer of 1942 and 1943. I managed to get information regarding 68 families; five of them contained two probands each, and so there were 73 probands. The families were investigated in geographical order so as to avoid subjective selection. I used to visit as many informants as was necessary for feeling reasonably confident regarding the presence or absence of a history of mental illness or of a major personality disorder in any one of the 601 uncles and aunts and the 144 parents (two fathers were unknown). Altogether more than 400 individuals served as informants, ranging from 3 to 12 per proband. Most of them were relatives or relatives-in-law from both sides of the family, and quite frequently they proved informed also regarding the side opposite to their own. The informants were chosen largely by availability, and the visits were made without notice. Out of the 353 living uncles and aunts, 114 were among the informants, and out of the 97 living parents, 93. As usual in rural populations, collaboration was mostly good and engaged.

Classification

I am indebted to three colleagues and friends, Eliot Slater of London, Torsten Frey of Uppsala, and Eberhard Nyman of Lund, for giving (1977) each separately their classification of the parents. This was intended as a test of my own classification of parents, uncles and aunts.

A twofold classification was used, one of personality and the other of mental illness. Only the latter has been considered sufficiently reliable to be included in the present paper, as follows:

D1. Classical schizophrenic psychosis or defect.
D2. Other psychosis suggestive of genetical kinship with schizophrenia (on the whole more acute, confusional, or emotional).
D3. Other functional psychosis (e.g. depressive or unspecified, also suicide with no further information).
D4. Mild functional mental illness (with preserved reality testing, 'neurosis').
D5. Mental illness mild or severe, of obvious or probable organic origin (e.g. old age dementia, alcoholic delirium, or following infection or childbearing).

The diagnoses were cumulative in the sense that every diagnostic group was successively included in the next group. Within each cumulated group all affected individuals were treated as if they had the same diagnosis, the most peripheral one from point of view of the schizophrenic spectrum being chosen. Table II shows the number of unilateral out of total families in each group.

Morbid risk

For the calculation of morbid risk (morbidity), the start of individual observation was put at the 15-year birthday for all uncles and aunts. For parents, the start of observation was at the age when they became parents of the respective proband (Weinberg, 1913; Essen-Möller, 1955, 1963). In exceptional instances where the onset was prior to parenthood, the age at onset was for convenience 'postponed' correspondingly. Otherwise the parents were treated as were the uncles and aunts. The end of observation was when the individual was last heard of.

In every five-year age group of relatives, the number of first incidences (relapses were not considered) was divided by the total time under risk in that age group. The rates (R) were converted into probabilities (P) according to the formula $P = 1 - e^{-Rw}$ where e denotes the base of the natural logarithms (2.718) and where w is the width of the age interval. The complements of these probabilities were successively multiplied through the age groups, and, in turn, the complements of the products indicated the cumulated morbid risks up to the lifetime risk (see Hagnell *et al*, 1981).

Depressive Syndromes in the Year following Onset of a First Schizophrenic Illness*

ALLAN HOUSE, JANET BOSTOCK and JOHN COOPER

A complete, unselected series of 68 patients who were seen during their first episode of an undoubtedly schizophrenic illness, and followed up one year later (for 56 patients) is described clinically. Depressive symptoms were common at onset, and 22% of patients could have been considered cases of depression from these symptoms alone. At follow-up, depressive symptoms had reduced in prevalence and only 7% of subjects were depressed cases. Only two cases of depression at follow-up had not been cases at onset. These changes could not be attributed to the use of antidepressants or ECT. Depressive syndromes could be distinguished from akinesia and the negative syndromes. The findings indicate that depression cannot be attributed solely to the administration of neuroleptics.

Depressed mood is a frequent finding in the aftermath of an acute schizophrenic episode, even in the absence of first-rank symptoms, a state often known as *post-psychotic depression* (McGlashan & Carpenter, 1976). Until recently, it has been widely accepted that neuroleptic medication is one important aetiological factor in what has come, therefore, to be known as *pharmacogenic depression*. It has been suggested that this 'post-treatment depression' may reflect a specific underlying pathophysiology in certain cases of schizophrenia (Galdi, 1983). Several detailed reviews of these issues have appeared recently in which the view of depression in schizophrenia as following the acute illness and being in some way tied up with its treatment or chronic sequelae has been challenged, most notably by Hirsch (Knights & Hirsch, 1981; Hirsch, 1982, 1984). These studies indicate that substantial levels of depression are found in first-onset acute schizophrenic illnesses and become less severe with the institution of neuroleptic medication. Relatively few patients have been shown to develop depressive syndromes *de novo* on neuroleptic medication.

The studies quoted by Hirsch are substantial, and their results are clear, but they can be criticised for the diagnostic criteria used, for relatively short follow-up periods, and most importantly for case selection. It may not be appropriate to consider relapses in chronic schizophrenia together with new acute schizophrenic episodes, or to take patients participating in a drug trial as representative of all schizophrenics.

Other problems in the phenomenology and classification of schizophrenia have been raised in the debate (Johnson, 1986). It has been suggested, for example, that the depressed mood is not strictly comparable to that found in the primary affective disorders but is really a variant of an extrapyramidal syndrome, so-called *akinetic depression* (Van Putten & May, 1978). The degree to which depression and akinesia can reliably be separated from each other or from the negative syndromes of slowing, affective blunting, social withdrawal and self-neglect is also a matter of some dispute.

It has been suggested that where insufficient attention is paid to diagnostic criteria there is over-inclusion of patients who would be better described as schizoaffective (Galdi, 1983), although this seems to beg the question of the nature of mood disorder in schizophrenia.

A recent review has emphasised the need for further research in all these areas (Johnson, 1986). The aim of the present study is to provide a detailed clinical description of an unusually complete group of patients seen during their first onset of an undoubtedly schizophrenic illness. Information obtained at onset and one-year follow-up is used to examine

(a) the prevalence of major mood disorder as part of the first illness in patients diagnosed as suffering from definite schizophrenia
(b) the natural history of any such mood disorder over the year of the follow-up, and in particular whether it is the same individuals who have mood symptoms at onset and at follow-up
(c) the degree to which depressive symptoms may be distinguished from akinesia and negative syndromes

---

*A report from the UK Field Research Centre of the World Health Organization Collaborative Study on Determinants of Outcome of Severe Mental Disorders.

(d) the relationship between depressive symptoms and the administration of neuroleptic medication.

Method

The 68 subjects were derived from a larger series of 99 patients making their first contact with Mapperley Hospital for a psychotic disorder as defined for the WHO collaborative study on Determinants of Outcome of Severe Mental Disorder (Cooper *et al*, 1987). The aim of the study was to identify and assess, in each of the catchment areas for a two-year intake period, individuals who met the following criteria:

(a) age 14–54
(b) residence of at least six months in the area in the year preceding the initial examination
(c) evidence of presence, in the preceding 12 months, of *at least one* of the following overt psychotic symptoms; hallucinations or pseudohallucinations in any modality; delusions; qualitative thought or speech disorder; qualitative psychomotor disorder; gross behavioural abnormalities representing a break in the person's previous pattern; a definite change of personality and behaviour during the last year, manifest in any of the following: loss of interests, initiative and drive leading to deterioration of performance; onset of social withdrawal, episodic severe excitement, purposeless destructiveness or aggression; episodic or persistent states of overwhelming fear or anxiety; gross and persistent self-neglect
(d) absence of clinical evidence of: organic cerebral disorder; CNS damage due to alcohol or drug abuse, manifest in encephalopathy, with or without polyneuritis
(e) first-in-lifetime contact with the defined psychiatric services of Nottingham within the last three months, occasioned by problems associated with the symptoms and behaviours enumerated in (b).

All patients who fulfilled the entry criteria and made contact within a two-year period were seen and assessed using the following instruments:

(a) Present State Examination (ninth edition) (PSE-9)
(b) Psychological Impairments Rating Scale (PIRS); this is an expanded and improved version of the behavioural items from PSE-9; it contains items relevant to behaviour, speech and interaction, covering such areas as body language, affect display, and facial expression (Jablensky *et al*, 1980)
(c) Disability Assessment Schedule (DAS); this is a social disability schedule designed for use by a trained interviewer and completed with the help of a near relative (Jablensky *et al*, 1980)
(d) Psychiatric and Personal History Schedule (PPHS); on this schedule is recorded basic demographic data, details of the presenting history, duration of symptoms and past medical history.

All patients were seen within 14 days of contact for the index illness and, where possible, within four weeks of the one-year follow-up date. A clinical diagnosis was made for each patient at entry to the study, and a current 'cross-sectional' diagnosis was made at the time of each of the one-year and two-year follow-up assessments. At these times, the entry diagnosis was also reviewed, in the light of any extra information about the onset of the illness that might have come to light in the intervening period, and which should have been available to the project diagnosticians at the time of entry (only one change was made in the entry diagnoses as a result of this review for the 68 patients in this report). The diagnoses were consensus diagnoses made at meetings of two or more experienced psychiatrists using the criteria of ICD-9, and potentially included a main and a subsidiary diagnosis, and, where appropriate, an alternative diagnosis to the main one. All the survey schedules and the hospital case-notes were available for these meetings.

The presence of main, subsidiary and alternative diagnoses allows the project diagnosis of these patients to be expressed in several different degrees of confidence for schizophrenia. A 'schizophrenia confidence' code was devised as follows:

(a) Schizophrenia certain: the main diagnosis is any of the schizophrenic categories except schizoaffective type (295.0–295.9, except 295.7), and no alternative diagnosis is given.
(b) Schizophrenia very likely: the main diagnosis is as for (a), but an alternative diagnosis is also given (any code).
(c) Schizophrenia probable: the main diagnosis is schizoaffective psychosis (295.7) or a paranoid psychosis (including psychogenic) (i.e. 297.0–297.9, 298.3, 298.4).
(d) Schizophrenia possible: the alternative diagnosis is a schizophrenic or paranoid category as in (a)–(c), but the main diagnosis is not.
(e) Not schizophrenic: neither main nor alternative diagnosis is any of the schizophrenic or paranoid categories.

For the purpose of this report, the first two categories of 'certain' and 'very likely' are combined, to give a group of 68 patients; for convenience, they are referred to here as having a diagnosis of 'definite schizophrenia'. The selection of these two groups means that the six patients with a diagnosis of schizoaffective schizophrenia are not included in this report.

A number of scores were derived from the PSE and PIRS:

(a) Four subscores were derived from the PSE: delusional and hallucinatory syndromes (DAH); behaviour, speech and other syndromes (BSO); specific neurotic syndromes (SNR); and non-specific neurotic syndromes (NSN), as in the CATEGO program. Table I indicates the constituent syndromes for these subscores.
(b) A 'total depression score' was defined as the sum of scores for the three PSE depressive syndromes: simple depression (SD); special features of depression (ED); and other symptoms of depression (OD).
(c) A 'clinical poverty score' was defined as the sum of the scores on the following syndromes: catatonic

TABLE I
PSE syndromes and subscores[1]

Abbreviation	*Definition*
DAH	*Delusional and hallucinatory syndromes*
NS	Nuclear syndrome
DD	Depressve delusions and hallucinations
AH	Auditory hallucinations
PE	Delusions of persecution
RE	Delusions of reference
GR	Grandiose and religious delusions
SF	Sexual and fantastic delusions
VH	Visual hallucinations
OH	Olfactory hallucinations
SC	Subcultural delusions and hallucinations
BSO	*Behaviour, speech and other syndromes*
CS	Catatonic syndrome
IS	Incoherence of speech
RS	Residual syndrome
AF	Affective flattening
HM	Hypomania
OV	Overactivity
SL	Motor slowness
NP	Non-specific psychotic syndrome
AG	Agitation
NG	Self-neglect
SNR	*Specific neurotic syndromes*
SD	Simple depression
ON	Obsessional syndrome
GA	General anxiety
SA	Situational anxiety
HT	Hysteria
ED	Special features of depression
NSN	*Non-specific neurotic syndromes*
DE	Depersonalisation
IR	Ideas of reference
TE	Tension
LE	Lack of energy
WO	Worrying etc.
IT	Irritability
SU	Social unease
IC	Loss of interest and concentration
HY	Hypochondriasis
OD	Somatic symptoms of depression

1. The 36 Present State Examination (PSE) syndromes are summed in four groups to derive components of the total score. The symptoms that make up the syndromes are listed by Wing *et al* (1974).

syndrome (CS); affective flattening (AF); slowness (SL); and self-neglect (NG).

(d) A syndrome of akinesia was derived from the PIRS. The syndrome comprised ten items related to psychic tempo, communication skills and speech. Details are available from the authors.

(e) The presence of extrapyramidal movements was also rated from the PIRS.

For further details of the symptoms that make up these syndromes and the methods of scoring the PSE, see Wing *et al* (1974).

Cut-off points for three of these scores were defined as follows.

(a) 'Clinical depression' was diagnosed if the total depression score was more than 5 in the presence of depressed mood (PSE symptoms 23 or 121).

(b) 'Clinical poverty' was diagnosed if the total poverty score was more than 2.

(c) Akinesia was diagnosed if the PIRS akinesia score was more than 2.

The 'clinical depression' definition corresponds to the checklist definition of depressed caseness derived by Finlay-Jones *et al* (1980). It was chosen because patients meeting its criteria would be considered to be sufficiently depressed to warrant description as cases in that respect alone regardless of any schizophrenic symptoms.

No such criteria exist for the definition of 'cases' of akinesia or clinical poverty, and we therefore took as the threshold the mean score for the group of patients who scored at all in the relevant syndrome groupings.

At one-year follow-up interview the same assessments were made. In addition, information on the medication that the patients had been prescribed in each month of the follow-up year was obtained from the PPHS.

Results

Onset data

There were 45 men and 23 women in the group. Nearly half of them were aged between 15 and 24 years (49%), 17 patients (25%) were aged between 25 and 34 years, and the rest were aged up to 55 years. Predictably, therefore, many of the patients were unmarried (68%), and 53% lived at home with their parents. The social class of the household head was defined according to the Registrar General's definition, and 18% of the group were in social classes I, II, and III (non-manual), while the rest were in skilled and unskilled manual categories of social class. At entry to the study, 75% of the group were in-patients.

A number of social and demographic factors were checked for significant association with any of the PSE syndromes, the PSE-derived subscores, or the PIRS-derived akinesia score. There was no association between any of these measures of psychiatric status and the patients' age, sex, marital status, social class, or occupation. As far as the illness itself was concerned, there was no association between any of the PSE or PIRS measures and the acuteness of onset as assessed on the PPHS, or the subtype of schizophrenia as defined using ICD-9 criteria.

The differences in initial presentation were sought between those eventually diagnosed as definite schizophrenics and others. PSE syndrome profiles for the definite schizophrenics and the other diagnostic groups are shown in Fig. 1. PSE and PIRS syndromes not part of the delusional and hallucinatory subgroup (DAH) were tested individually for their association with a final diagnosis of 'definite schizophrenia' or 'any other diagnoses' using corrected χ^2. The principal finding was that hypomania

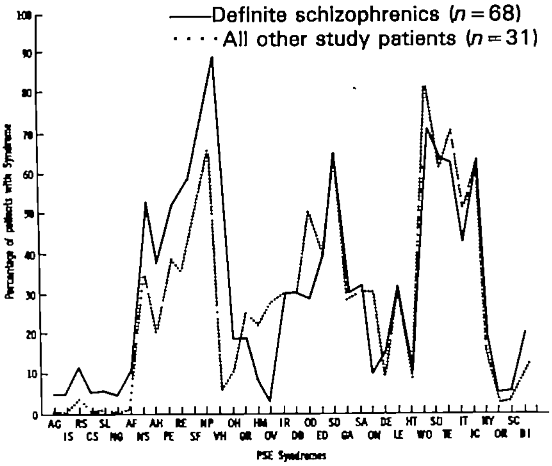

Fig. 1 PSE syndrome profiles (percent prevalence) at onset.

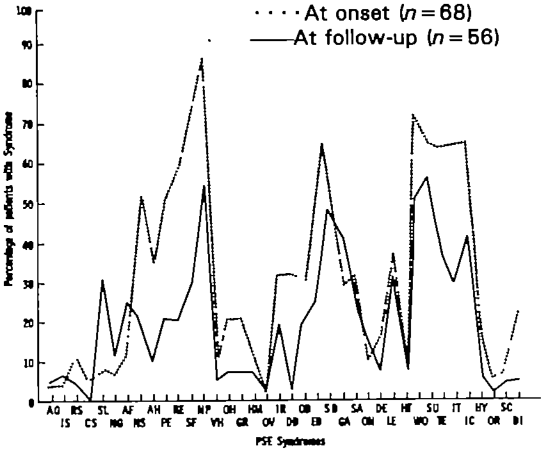

Fig. 2 PSE syndrome profiles (percent prevalence) for definite schizophrenics.

(HM) and somatic symptoms of depression (OD) were associated with all diagnoses except definite schizophrenia ($P<0.05$). Other mood symptoms were unrelated to diagnosis, while affective flattening (AF), residual syndrome (RS) and akinesia were associated with a final diagnosis of definite schizophrenia ($P<0.05$).

Non-psychotic syndromes at onset

The onset data were examined to determine the degree to which the depressive syndromes, negative syndromes and akinesia could be distinguished from each other, by testing the correlations between all these PSE syndromes for the 68 patients. The specific depressive syndromes and the non-specific dysphoric syndromes tended to be significantly associated with each other, as shown in Table II. None of these depressive or dysphoric syndromes was correlated with any of the negative syndromes or akinesia, at the 5% significance level.

At onset, 15 of the 68 definite schizophrenic patients (22%) were defined as depressed cases by the criterion adopted here. In comparison, 23 patients (34%) fulfilled Hirsch's criterion of a score on at least three of the PSE depressive syndromes (a broader definition because depressed mood itself was not a prerequisite). Twenty-one patients (31%) had some score on the syndrome 'other features of depression' (OD), which comprises the biological symptoms of depression.

One-year follow-up data

Of the original 68 'definite schizophrenics', 56 were available for follow-up interview at one year. Their PSE syndrome profiles are shown in Fig. 2. The 12 patients unavailable for PSE interview at follow-up did not differ substantially from the overall group with regard to their syndrome profiles or other characteristics at onset.

The prevalence of delusional and hallucinatory syndromes (DAH) and of behaviour and speech disorder (BSO) was reduced in the follow-up period, such that for the group as a whole there was no association between onset and follow-up scores for DAH and BSO.

Similarly there was a decrease in prevalence both of depressive and of other neurotic syndromes. In particular, only five patients at follow-up were considered depressed cases; three of these had been definite and one a borderline case at onset (see Table III). The number of patients with any biological symptoms of depression had fallen from 21/68 (31%) to 11/56 (20%).

Three subjects who were diagnosed as depressed cases at onset could not be interviewed at follow-up; two had left the area and lost contact and one was in prison, reportedly still in a depressed, withdrawn state and receiving antidepressant medication. Of the other nine subjects not available for PSE interview at follow-up, three had left the area, five declined interview and one was in prison. In other words, there is no good evidence that the prevalence of depression fell at follow-up because of failure to interview the most depressed subjects.

By contrast, both clinical poverty and akinesia became more prevalent in the group. Numbers of patients with a clinical poverty score >2 had increased from three to nine and with an akinesia score >2 from 31 to 38.

Symptoms and medication

Any association between clinical picture at follow-up and recent medication was sought by comparing those patients who had been prescribed neuroleptics consistently throughout the second six months of the follow-up period with those who had not. Complete information on neuroleptic medication was only obtainable for 46 of the follow-up group. The numbers involved were too small to assess the relationship between depression or clinical poverty and neuroleptic medication. However, as shown in Table IV, both akinesia and the subscore BSO were associated with neuroleptics.

Of the 68 definite schizophrenic patients, 11 patients received a course of antidepressant medication for three consecutive months at some time during the follow-up year.

Of these 11, only five were depressed cases at onset (subjects 012, 037, 047, 097, 099), and two remained depressed at follow-up. None of the four patients who received ECT during the year were depressed cases at onset or follow-up; two received treatment for symptoms of withdrawal and neglect with little overt depression, one for a state of catatonic excitement, and one for depressive symptoms of non-caseness severity occurring in the puerperium. All four received ECT within two months of onset. In other words, the reduction in prevalence of depression at follow-up could not be attributed solely to specific treatments for depressive illness.

Discussion

Discussions about the meaning of mood disorder in schizophrenia have been hampered by uncertainties about diagnostic validity or selection bias in the group studied. The present group of patients represents an unselected, consecutive series of contacts with Mapperley Hospital, which serves a diverse, mainly urban population. All contacts were for the first onset of psychotic disorder: they were not acute relapses of previously known patients. Diagnostic uncertainty was kept to a minimum by the two-year follow-up period and the use of consensus meetings of experienced psychiatrists to arrive at clinical diagnoses based on the operational criteria of a standard classification. This diagnostic process led to exclusion from the group of 'definite schizophrenia' of patients with major mood disorders at onset. For example, syndrome profiles show that the presence of hypomania (HM) or biological symptoms of depression (OD) was significantly less common in the 'definite schizophrenia' group than in those with any other diagnosis. The frequency of both these syndromes in the group was less than that noted for a population diagnosed as schizophrenic using CATEGO and on the basis only of onset of mental state (Knights & Hirsch, 1981).

Despite this proviso, patients with a diagnosis of definite schizophrenia had a wide range of dysphoric symptoms with an essentially similar distribution and frequency to those without such a diagnosis. Despite differences in case selection and diagnostic criteria, the clinical syndrome profile of our patients was similar to that of those described by Knights & Hirsch (1981).

At one-year follow-up there was a substantial reduction in the specific and non-specific dysphoric syndromes, so that relatively few patients continued to display a clinically significant depressive disorder. Nonetheless, minor dysphoric symptoms remained common. The time interval between the two interviews does not preclude the possibility of a brief but major depressive episode emerging in the months after acute onset and resolving spontaneously or with phenothiazines (Mandel *et al*, 1982).

The negative syndromes present a more complicated picture. They were present at first onset in some patients, so they cannot be considered solely as a consequence of chronicity or of prolonged neuroleptic medication. Nonetheless, their prevalence increased at follow-up, when there was a significant association with neuroleptic medication even in the absence of Parkinsonian symptoms. This suggests one of the following: (a) that the negative syndromes are drug-induced in some patients, (b) that they cannot always be reliably separated from drug-induced akinesia, or (c) that patients who are more prone to develop these syndromes have other features which make it more likely that they will be prescribed neuroleptics. The observational nature of the present study did not allow a further examination of these possibilities.

The question remains as to what part neuroleptic medication has to play in depression. There is no evidence from our data that depressive syndromes were related to concurrent neuroleptic medication. This finding is in keeping with ideas of revealed or co-existent depression (Knights & Hirsch, 1981; Ndetei & Singh, 1982) and provides no support for the concept of pharmacogenic depression.

In summary, these findings demonstrate that the depressive disorders so commonly seen in the follow-up of schizophrenic patients are present at first onset, and that those patients who are depressed at follow-up are the same individuals who were depressed at onset. Few new cases of depression emerge at follow-up, and in fact the prevalence of depression reduces with time. The depressive syndromes can be reliably separated from akinesia and clinical poverty, which by contrast increase in prevalence at follow-up and are associated with the taking of neuroleptics. The purpose of the study at the time these ratings were made was not specifically to examine depressive or negative syndromes in schizophrenia, and therefore this differential behaviour of the two syndrome groups is unlikely to have been due to rater bias.

Taken together, these findings argue against the suggestion that neuroleptic medication is important in causing depression in schizophrenia, either in a manifest form or in a disguised form such as akinetic depression.

Acknowledgements

We are grateful to the consultant staff of the Mapperley group of hospitals and to all grades of medical, clerical and administrative staff. The study was supported in part by grants from the Division of Mental Health, World Health Organization, and from the Department of Health and Social Security.

Prediction of Outcome in Depressed Patients by Weekly Monitoring with the Dexamethasone Suppression Test

I. SCHWEITZER, K. P. MAGUIRE, A. H. GEE, J. W. G. TILLER, N. BIDDLE and B. DAVIES

Forty-three depressed patients in hospital were studied with weekly dexamethasone suppression tests (DSTs) and were followed as out-patients for at least three months after discharge. The detection rate of patients with LHPA axis dysfunction increased from 41% with a single DST to 59% with serial DSTs. There was a poor correlation between weekly post-dexamethasone cortisol levels and Hamilton depression rating scores. In patients with evidence of LHPA axis dysfunction, a DST at discharge discriminated effectively between a good and a poor outcome group; persistent non-suppression was strongly linked with a relapse of depression in the first three months after discharge. In general, our results support previous claims that the DST is a state marker for depressive illness.

Extensive research which originated in the 1960s (Carroll *et al*, 1968; Carroll & Davies, 1970; Sachar, 1967) has resulted in the finding that approximately 50% of patients suffering from a major depressive illness have an associated abnormality of functioning of the limbic–hypothalamic–pituitary–adrenal (LHPA) axis. Evidence, including recent studies with the corticotropin releasing factor stimulation test, suggests that the dysfunction originates from centres at or above the hypothalamus (Holsboer *et al*, 1984; Gold & Chrousos, 1985). The outcome of these studies has been the widespread clinical application of the dexamethasone suppression test (DST) as standardised by Carroll *et al* (1981). The popularity of the DST as a measure of LHPA axis dysfunction in depression has resulted from its simplicity and ease of application. Recently, a greater awareness has grown (Berger *et al*, 1982; Hirschfeld *et al*, 1983; Braddock, 1986) of several intervening variables which may cause difficulties in interpretation of results. These variables, such as false positives and negatives, dexamethasone concentrations, and drug withdrawal, have imposed limitations on the DST's principal clinical use as a diagnostic tool.

The DST has also been used to monitor and predict treatment response; however, this aspect of the DST has not been extensively investigated. Carroll *et al* (1976*a*,*b*) reported three cases of normalisation of the DST response following recovery from depression, and this observation has been repeated in several studies (Albala & Greden, 1980; Greden *et al*, 1980; Albala *et al*, 1981). Non-suppression of the DST at discharge has been linked with a poor response to treatment, increased likelihood of a relapse of symptoms following discharge, and increased suicide risk (Goldberg, 1980*a*,*b*; Yerevanian *et al*, 1984; Nemeroff & Evans, 1984; Targum, 1984).

There have been four detailed reports in which depressed patients were systematically monitored while in hospital with serial (mostly weekly) DSTs (Holsboer *et al*, 1982; Greden *et al*, 1983; Bowie & Beaini, 1985; Gerken *et al*, 1985). All concluded that normalisation of the DST response was linked with good treatment outcome. Greden *et al* (1983) reported a correlation between decreasing post-dexamethasone cortisol levels and decreasing ratings of severity of depression. These findings suggest that the DST may be a biological state marker for the episode of a depressive illness in the monitoring of treatment response. In the capacity of monitoring patient progress, the previously mentioned limitations of the test are less crucial, especially if intervening variables remain stable.

In this report we present data on 43 depressed patients who had weekly DSTs while in hospital. As our aim was to investigate the prognostic implications of changes in DST status, we have included follow-up, post-discharge data. In this study, treatment and discharge decisions were made solely on clinical grounds, without reference to DST results.

Method

Patients

Over a one-year period, 43 patients admitted to the Psychiatric Unit of the Royal Melbourne Hospital with a primary diagnosis of Major Depressive Disorder were studied. All patients were assessed by two senior psychiatrists using DSM-III (American Psychiatric Association, 1980) diagnostic criteria. Patients had a detailed physical examination and laboratory screening tests to exclude serious physical disorder. Carroll's exclusion criteria (Carroll *et al*, 1981) were applied. Only those patients who completed at least three weeks of treatment have been included. Although not all patients studied were initially medication-free, none were receiving drugs which are known to influence dexamethasone kinetics. Informed consent was obtained from all patients.

DST

During the first week (but not before the third day following admission) all patients received a standard DST as specified by Carroll *et al* (1981), with 1 mg of dexamethasone being administered at 23:00 and blood samples for plasma cortisol being taken the same and the following day at 16:00. Plasma cortisol was analysed in the Department of Biochemistry (Royal Melbourne Hospital) using the routine assay (Amerlex; Amersham, UK). The DST was repeated at approximately weekly intervals while the patients were in hospital.

Definition of non-suppression/suppression status

In this report we have based our definition of cortisol non-suppression on the result of a previous study in this department of 100 normal volunteers (Tiller *et al*, in preparation). Volunteers received a standard DST and the criterion value was determined using Carroll's (1985) recommendation that 5% of a normal population are taken to be non-suppressors. The derived criterion value was 170 nmol/l. In the region around the criterion value, the confidence with which an individual can be classified as a suppressor or non-suppressor is low. Such an interval was defined using the coefficient of variation for cortisol at 170 nmol/l, which was approximately 5% for the Amersham kit used in this study. Therefore, we have classified post-dexamethasone plasma cortisol values above 187 nmol/l as non-suppression and values below 153 nmol/l as suppression, with at least 95% confidence. Plasma cortisol values between these limits have been excluded from analysis.

Clinical ratings

Patients received weekly assessments on the 17-item Hamilton depression observer-rating scale (HDRS) and the Carroll depression self-rating scale. Assessors were blind to the laboratory DST results. All patients scored 17 or higher on the HDRS for admission into the study.

Patient case records were studied for post-discharge follow-up data and whenever possible this was supplemented by consultation with the treating psychiatrist. We defined relapse as a recurrence of those symptoms that had led to the patient's original admission; the symptoms were judged to be of such severity to warrant either readmission to hospital or an increase in dose or change of medication and closer out-patient supervision.

Weight assessment

A careful history of recent weight loss was recorded at admission. All patients were weighed and their heights measured at admission, and they were weighed weekly while in hospital.

Treatment

All patients received standard antidepressant treatment; that is, electroconvulsive therapy (ECT) or antidepressant medication. Courses of ECT ranged from 6–15 applications. All patients were maintained on antidepressant medication (lithium carbonate, tricyclics or monoamineoxidase inhibitors) during the out-patient follow-up period. All treatment decisions were made by the treating clinician.

Data analysis

Variables were tested for normality using the Kolmogorov–Smirnov one-sample test, and parametric or non-parametric tests were used where appropriate. Independent *t*-tests were used for group comparisons, and Pearson's product moment correlations for testing significance of relationships between variables. The significance level was set at $P<0.05$ for comparisons and at $P<0.01$ for correlations.

Results

Categorisation of patients

On the basis of the initial DST result, of the 43 patients studied, 24 patients had a suppressor response and 17 a non-suppressor response. Two patients had post-dexamethasone plasma cortisols within the region of unreliability and were excluded from the analysis.

FIG. 1. Categorisation of patients.

When serial DST responses were considered, there were seven patients with initial suppressor responses which were followed on subsequent weeks with at least two consecutive non-suppressor responses. As this indicated LHPA axis dysfunction, we have consequently studied these delayed non-suppressors with the initial non-suppressors (Fig. 1). Recategorisation gave 24 patients with evidence of LHPA axis dysfunction (group A) and 17 without such evidence (group B). Therefore, the detection rate of depressed patients with an abnormality of LHPA axis functioning was increased from 41% with a single DST to 59% with serial DSTs.

Group A and B categories did not differ significantly in age, baseline severity of depression as reflected by HDRS, weight, or history of recent weight loss (Table I).

TABLE I

Comparison of group A and group B patients

	Group A ($n=24$)		*Group B* ($n=17$)		*P*
	Mean	*s.d.*	*Mean*	*s.d.*	
Age: years	62.0	12.2	59.0	14.3	NS
Weight: kg	59.3	10.8	63.1	16.8	NS
Weight loss (pre-admission): kg	2.4	2.3	1.8	3.4	NS
HDRS	27.6	5.7	27.5	4.5	NS
Pre-dexamethasone cortisol: nmol/l	453	143	338	140	0.016

There was no relationship between the patients' sex and group A or B status. Seven group A and five group B patients were male ($\chi^2=0.389$, NS). There was no difference in choice of treatment between the two groups, A patients being no more likely to receive ECT than B patients, 14 As and 11 Bs receiving ECT ($\chi^2=1.42$, NS). The median stay in hospital was five weeks for both groups.

Comparisons of post-dexamethasone cortisols and HDRS

The relationship between mean post-dexamethasone plasma cortisols and mean HDRS scores over four consecutive weeks was examined in the 16 group A patients who had complete records. There was a tendency for cortisol and HDRS scores to fall together, but this did not reach statistical significance ($r=0.832$, $P=0.08$).

There were no significant correlations between post-dexamethasone plasma cortisols and HDRS scores at weeks 1–4 for group A or B patients; for example, group A at week 1, $r=0.083$, $P=0.351$. Similarly, there were no significant lag correlations between the variables over the four weeks, correlations ranging from $r=-0.131$ ($P=0.314$) to $r=0.234$ ($P=0.191$) for group A and from $r=-0.198$ ($P=0.313$) to $r=0.218$ ($P=0.286$) for group B.

Normalisation of the DST response in group A patients

At discharge, 15 of the 24 patients with evidence of LHPA axis dysfunction (group A) were suppressing cortisol normally (normalisers), while 7 had a non-suppressor response (persistent non-suppressors). Two patients had intermediate post-dexamethasone plasma cortisol levels at discharge and were not subclassified (Fig. 1). The mean HDRS of the persistent non-suppressors (13 ± 7) tended to be higher than that of the normalisers (11 ± 6), but the difference did not reach statistical significance. Discharge weights and mean hospital stay were similar in these two subcategories. Also, there had been no difference in choice of treatment during hospital stay: four persistent non-suppressors and eight normalisers received ECT ($\chi^2=0.082$, NS).

Three-month post-discharge follow-up

Follow-up post-discharge data were available on 13 group B and 20 group A patients. A relapse of the depressive illness occurred in six group A and three group B patients; this result was non-significant ($\chi^2=0.016$, NS).

However, in patients with evidence of LHPA axis dysfunction (group A subjects), serial DSTs discriminated between those who were likely and those not likely to suffer a relapse of depression. Only one of 13 normalisers relapsed, while five of the seven persistent non-suppressors suffered a relapse. This result is highly significant (Fisher's exact: $P=0.006$). There was no significant difference in mode of out-patient treatment between the two subcategories; neither normalisers nor persistent non-suppressors were more likely to receive lithium carbonate or other antidepressant therapy. Three of the 13 normalisers and two of the seven persistent non-suppressors were prescribed lithium carbonate ($\chi^2=0.073$, NS).

Discussion

In this report we present data on 43 depressed patients who were followed with serial DSTs while in hospital. Our results support previous work which concludes that the DST is a biological state marker for some patients who have a depressive illness.

In our patient sample, a DST shortly prior to discharge was able to effectively distinguish a poor outcome from a good outcome group. For patients who were persistent non-suppressors there was a significantly increased likelihood of relapse in the first three months following discharge. Most patients (92%) whose DST response normalised while they were in hospital progressed well after leaving hospital. These findings are in keeping with previous work, such as that of Yerevanian *et al* (1983), who reported on ten patients who were non-suppressors at discharge. Nine of the ten, in their report, did poorly following discharge, with three patients committing suicide. Our study has provided further evidence for the predictive value of the DST by including a comparison outcome group of normalisers, thereby establishing the highly significant difference in outcome between normalisers and persistent non-suppressors.

The weight of current evidence suggests that a non-suppressor response at discharge indicates inadequate or incomplete treatment of the depressive illness. These patients are a high-risk group and we recommend either further in-patient assessment or careful out-patient supervision, such as weekly appointments. To further investigate these conclusions we suggest that there is an important need for outcome research where such patients are followed prospectively with out-patient DSTs.

It is pertinent to mention those few patients whose clinical course was inconsistent with the above findings. There were two persistent non-suppressors who remained well following discharge. In both of these cases, reductions in post-dexamethasone cortisol levels of over 50% had in fact occurred during their hospital stay. It is possible that their DST responses may have normalised shortly after discharge, but we do not have data to support this contention. The one normaliser who relapsed did so near the end of her three-months follow-up.

A principal purpose of a state marker in medicine is to monitor improvement in the underlying pathophysiological process of a particular condition (Galen & Gambino, 1975). Clinical symptomatic status has limitations in following response to treatment because of its subjectivity and vulnerability to influence from a multiplicity of factors. Consequently, serial testing has widespread application in medicine, monitoring recovery in conditions such as anaemia, myocardial infarction, diabetes, and uraemia. In depressed patients with evidence of LHPA axis dysfunction, there is a general group trend for normalisation of the DST response and clinical improvement to parallel each other during hospital stay; however, there is no clear relationship when patients are considered on an individual basis. This finding is consistent with previous work (Gerken *et al*, 1985; Bowie & Beaini, 1985). For some depressed patients, the non-specific aspects of being in hospital and the psychosocial interventions may result in a temporary amelioration of symptoms. Therefore the relatively poor correlation between HDRS (an essentially clinical assessment) and post-dexamethasone cortisol does not in fact detract from the DST's usefulness in monitoring response to treatment. Our results suggest that if a non-suppressor response persists at discharge in a patient with major depression, the biological aspect of the illness has been inadequately treated.

In this study we found that the detection rate of depressed patients with an abnormality of LHPA axis functioning increased from 41% with a single DST to 59% with serial DSTs. Greden *et al* (1983) reclassified three of 31 subjects from suppressor to non-suppressor status on the basis of a repeat DST. They attributed the change in DST status to anti-depressant withdrawal, regarding these patients as having been partially treated. It is likely that this was a factor with at least some of our reclassified patients. The DST is a sensitive, dynamic test, primarily of the feedback mechanism of the LHPA axis. The DST is vulnerable to a variety of influences, including technical errors and possibly unknown factors, which may cause both false positive and false negative results. The need to perform repeated tests is well recognised in certain medical conditions. For instance, several blood tests are often required to confirm a diagnosis of hypercalcaemia (Potts, 1983). The application of serial DSTs described here, for improved detection of depressed patients with LHPA axis dysfunction, has not been previously emphasised and needs further investigation.

Acknowledgements

We are grateful to the medical and nursing staff of the Royal Melbourne Hospital Psychiatric Unit for their support during the project, to Dr D. Campbell and the Department of Biochemistry for the cortisol determinations, and to Ms R. Apa for the collection of blood samples.

in Prescribing Information ▼ **Presentation:** Round, yellow, enteric-coated tablets each
ing 50mg fluvoxamine maleate, imprinted with 'Duphar 291'. Pack of 60 tablets, basic NHS price
Uses: Treatment of those affective disorders characterised by persistent low mood, impaired
notor activities and psychosomatic complaints. **Dosage and Administration:** The tablets should
llowed without chewing and with water. Adults: The effective daily dose usually varies between
and 200mg and should be adjusted to the individual response of the patient up to a maximum of
The minimum recommended starting dose is 100mg given in the evening. A total daily dosage in
of 100mg should be given in divided doses. Elderly: The same dosage regimen may be utilised in the
as in the general population. Children: There are insufficient data to recommend the use of Faverin in
. **Contra-indications, Warnings, etc:** Faverin should not be given together with or within two
of terminating treatment with monoamine-oxidase inhibitors. Patients with hepatic or renal
iency should begin treatment with a low dose and be carefully monitored. Faverin has no effect on
notor skills associated with driving and operating machinery. However, in combination with alcohol
npairment may be seen. Use in pregnancy and lactation: There has been little human use but there
en no adverse animal evidence. Avoid in pregnancy and in nursing mothers if a better known and safer
ive is available, although safety in pregnancy is likely. Interactions with other drugs: In interaction
studies increased plasma levels of propranolol and warfarin were seen during concurrent adminis
Faverin. Care should be taken when Faverin is prescribed to patients already receiving propra
warfarin as the dose of these drugs may need to be lowered. No interactions were seen with digox
atenolol. **Side-effects:** The commonest symptom observed with Faverin administration is naus
usually diminishes early during the course of treatment. Other treatment emergent symptoms
during clinical studies were somnolence, constipation, agitation, anorexia and tremor. Other report
are often associated with the illness and their incidence in controlled trials is comparabl
experienced with placebo. Faverin may cause a decrease in heart rate. During treatment, limited
repolarization were observed in the ECG, but no causal relationship could be demonstrated. The in
postural hypotension was similar to that seen in patients treated with placebo. Treatment of overd
specific antidote is known. The stomach should be emptied as soon as possible after tablet inge
symptomatic treatment should be given. The use of medicinal charcoal is also recommended.
Quantities 50mg tablets: available in packs of 60 (3 strips of 20 blister-packed tablets). **Product**
Number 50mg tablets: 0512/0070. Further information is available from: Duphar Laboratorie
Duphar House, Gaters Hill, West End, Southampton SO3 3JD. Tel: Southampton (0703) 472281.

Faverin.® Specific action on brain metabolism may explain its many dvantages in the treatment of depressior

FAVERIN®
fluvoxamine

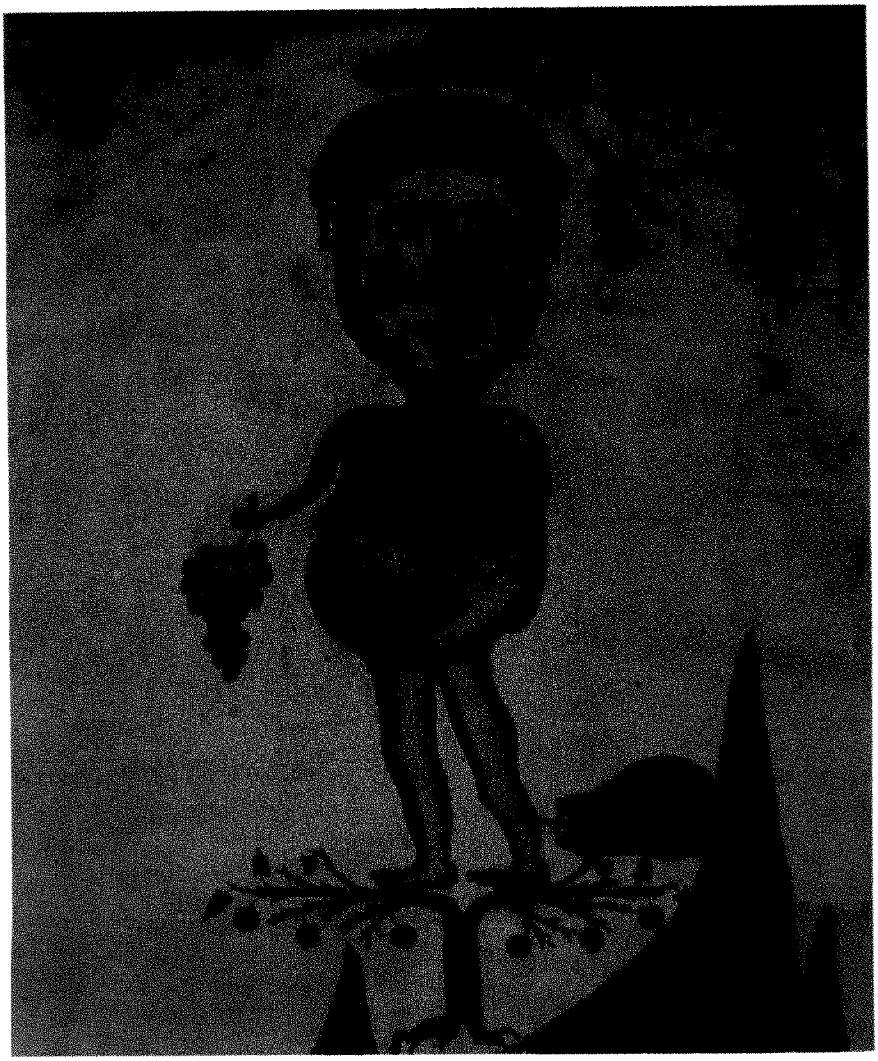
Highly Selective 5-HT Reuptake Inhibitor

AN EXPRESSION OF SCHIZOPHRENIA.

Heinrich Anton Müller, was admitted to the Mental hospital at Munsingen at the age of 41 where he remained until his death in 1930.

He was said to be subject to delusions of grandeur and a persecution complex, signing himself as "God" or as "L'Eternal." From 1912 he occupied himself with drawings and constructing enormous machines of no apparent use.

The picture below is reproduced with kind permission of the Museum of Fine Art, Berne.



A TREATMENT.

Haldol* Decanoate administered as a single deep intra-muscular injection provides a consistent 4 week duration of action.

An initial dose of 50mg every four weeks is recommended, increasing if necessary after two weeks by 50mg increments to 300mg every four weeks. The four weekly dose should reflect the total dose given in the first four weeks of treatment. In patients with severe symptomatology or in those who required large oral doses for maintenance medication, higher doses of Haldol* Decanoate may be required.

The schizophrenic patient can benefit from a therapy with little incidence of sedation[1] and a reduced requirement for antiparkinsonian medication[2] leaving him/her better able to participate in other forms of therapy.

For example when 35 patients receiving fluphenazine decanoate 3-weekly were given instead Haldol* Decanoate 4-weekly: "A total of 18 patients could successfully be withdrawn from previously used antiparkinsonian medication . . . without experiencing an exacerbation of extrapyramidal side-effects and their psychotic symptoms continued to be well controlled."[3]

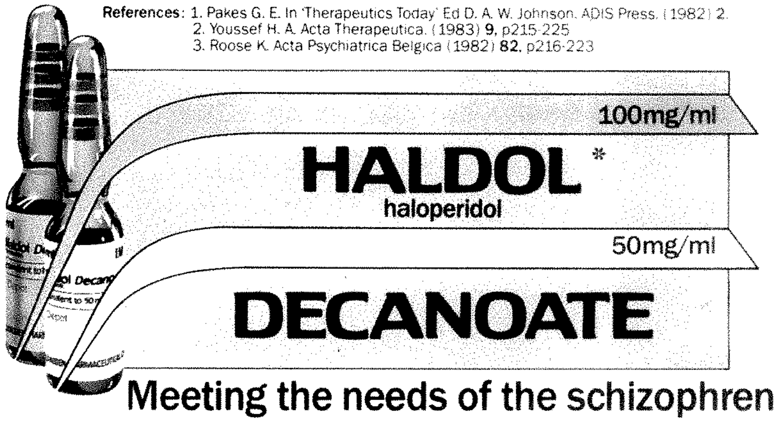
3. Roose K. Acta Psychiatrica Belgica (1982) **82**, p216-223



Meeting the needs of the schizophrenic.

Presentation: Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses**: As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side effects, precautions, contra-indications**: Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side effects: In common with all neuroleptics, the following side effects may be observed, sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Occasional local reactions such as erythema, swelling or tender lumps have been reported. In common with other anti psychotics, haloperidol has been associated with rare cases of neuroleptic malignant syndrome. **Dosage**: Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. An initial dose of 50mg every 4 weeks is recommended increasing if necessary after 2 weeks by 50mg increments to 300mg every 4 weeks. The dosage should be tailored to suit the individual patient and to reflect previous oral dosage. In adults 100mg Haldol* Decanoate is approximately equal to 500mg chlorpromazine (or equivalent) per day. Caution is required with the elderly, starting doses of 12.5mg to 50mg monthly should be tried first. **Product Licence Numbers**: 0242/0095, 0242/0094 **Basic NHS Cost**: 1ml x 100mg/ml x 5 £24.00 1ml x 50mg/ml x 5 £15.60. (Correct at time of printing). Further information is available on request from: **Janssen Pharmaceutical Limited**, Grove, Wantage, Oxon OX12 0DQ.

Major Affective Disorder in Anorexia Nervosa and Bulimia

A Descriptive Diagnostic Study

REINHOLD G. LAESSLE, SUSANNE KITTL, MANFRED M. FICHTER,
HANS-ULRICH WITTCHEN and KARL M. PIRKE

DSM–III lifetime diagnoses were assessed in 52 patients with a lifetime history of anorexia nervosa or bulimia by means of a standardised diagnostic interview. It was found that 44.2% had a lifetime diagnosis of DSM–III major affective disorder, with abstaining anorectics having a lower rate of depression than those with bulimic symptoms. In the great majority of cases, the onset of affective disorder post-dated the onset of the eating disorder by at least one year. In patients whose eating disorder was in remission, the rate of depressive symptoms was lower than in those in the acute stage of their illness. These findings, combined with recent studies on biological changes in eating disorders, and psychological theories of depression, suggest that in most cases in which the two conditions are associated, the depression is secondary to the eating disorder.

The possibility of a close relationship between the two eating disorders and major affective illness has been the subject of considerable recent interest (e.g. Swift *et al*, 1986), and the hypothesis that anorexia nervosa and bulimia are each a variant of affective disorder has been suggested by several authors (Cantwell *et al*, 1977; Hudson *et al*, 1983). Evidence for this association is provided by neuroendocrine similarities, the response of eating disorder patients to antidepressant medication, family studies, and psychopathological observations of the frequent occurrence of depressive symptoms in the acute stage of an eating disorder. However, the conclusion that eating disorders are a variant of or secondary to affective disorders has been questioned. Neuroendocrine abnormalities both in major depression and eating disorders may be due to various behavioural factors such as the quantity, quality and temporal ordering of nutrition (Pirke *et al*, 1985), exercise (Bullen *et al*, 1985), or stress (Rose, 1984). Other authors have shown that only a small proportion of patients with anorexia nervosa or bulimia respond to antidepressant medication (Sabine *et al*, 1983; Fairburn, 1984), and a recent well-controlled family study found rates of affective disorder in relatives of eating disorder patients to be no higher than those in relatives of normal controls (Stern *et al*, 1985).

Data on psychopathological relationships have to be interpreted with care. In most studies, 'depression' in eating disorder patients has been assessed by means of self-report scales like the Beck Depression Inventory or MMPI subscales, which do not allow syndromal diagnosis of affective disorder. Studies using operational diagnostic criteria have shown great variability in rates of major affective disorder in acute eating disorder patients (for review see Strober & Katz, 1986), and the nature of the relationship between the two illnesses remains unclear. The available data could well be interpreted as indicating that the depression is a consequence of or reaction to the psychopathological and biological characteristics of the eating disorder. Clarification necessitates consideration of the rate of affective disorder not only in the acute stage of eating disorder, but also at other times during the patient's life. Attention must also be paid to the temporal relationship between onset of the eating disorder and the onset of affective illness. Furthermore, patients should be studied for the persistence of depressive symptoms after successful treatment of their eating disorder. The aim of this study is to investigate the psychopathological relationship of affective disorder to eating disorders using standardised diagnostic assessment and DSM–III diagnostic criteria.

The following questions are dealt with: (a) How large are the lifetime rates of major affective disorders in patients with different types of eating disorder? (b) Does the onset of major affective disorder precede the onset of eating disorder? (c) Is the rate of major affective disorders lower in patients after treatment of their eating disorder than before?

Method

Subjects were 52 consecutive individuals who met DSM–III criteria (American Psychiatric Association, 1980) for anorexia nervosa, bulimia or both disorders at any point in their lifetime. Characteristics of the total sample and

subgroups are shown in Table I. All but one patient in the group with anorexia nervosa plus bulimia were female. Thirty-five of the patients were interviewed for the study as in-patients within the first two weeks of admission, the remaining 17 as out-patients at a follow-up one year after discharge from hospital. Patients were treated on open psychiatric wards at either the Max Planck Institute of Psychiatry or the Psychiatric University Hospital in Munich. Diagnostic assessment was made using the German version of the Composite International Diagnostic Interview (CIDI), which is an expanded form of the National Institute of Mental Health Diagnostic Interview Schedule (DIS) (Robins *et al*, 1981). The CIDI/DIS is a standardised instrument of demonstrated reliability (Semler *et al*, 1987) and enables computerised DSM-III diagnoses. All patients were assessed for eating disorder by two psychometric questionnaires, the Eating Disorder Inventory (EDI; Garner *et al*, 1983) and the Eating Attitudes Test (EAT; Garner *et al*, 1982). The CIDI/DIS interviews were conducted by one of the first two authors (RGL, SK). There were no significant differences between the two interviewers in the rate of diagnosing any DSM-III disorder.

A control group for lifetime frequency of depressive symptoms was formed of 47 patients (all female; mean age 27.3 years, s.d. 3.8) with a DSM-III diagnosis of major depression, but without a lifetime diagnosis of an eating disorder, who had been treated at the Max Planck Institute of Psychiatry and who were also interviewed with the CIDI/DIS.

Relative frequencies were compared for statistical significance using Fisher's exact test with Tocher's modification. Significance levels are one-tailed. To obtain correct levels of significance in the case of multiple tests between groups, alpha was adjusted according to the Bonferroni–Holm method. The eight subscales of the EDI and the three subscales of the EAT, respectively, were compared simultaneously between in-patients and out-patients by Multivariate Analysis of Variance (MANOVA).

Results

DSM-III diagnoses found in the groups studied are shown in Table II. Significant differences between subjects with anorexia nervosa only and those with anorexia plus bulimia were found in lifetime rates of major affective disorder ($P<0.02$) and total affective disorder ($P<0.03$). There was a significant difference between pure anorexics and pure bulimics in the lifetime rate of substance use disorders ($P<0.05$). The highest lifetime rates of major affective disorder were found in subjects with anorexia plus bulimia, the lowest in patients with anorexia nervosa only. Comparison of lifetime frequency of depressive symptoms for the three eating disorder groups revealed statistically significant differences (adjusted $P<0.05$) in symptom frequency for only two symptom areas: patients with only anorexia nervosa had a lower frequency of "feelings of worthlessness, self-reproach or guilt" (15.4%) than patients with anorexia plus bulimia (69.2%) and those with bulimia only (69.2%); they also had a lower frequency of "wishes to be dead" (7.7%) than patients with anorexia plus bulimia (57.7%). In general there was a tendency towards higher symptom rates for patients with anorexia nervosa plus bulimia than in the other two groups. Statistical comparison of all three eating disorder groups to the control group with only major depression showed significantly lower frequencies (adjusted $P<0.05$) for the eating disorder group in four areas: "loss of appetite" (eating disorders 34.6%, major depression 66.0%), "loss of energy" (42.3% *v.* 85.1%), "slowed thinking" (34.6% *v.* 72.3%) and "suicide attempts" (21.1% *v.* 65.2%).

Among the 23 patients with a lifetime diagnosis of major affective disorder, the onset of the affective disorder post-dated the onset of the eating disorder by at least one year in 16 cases (69.6%) and occurred within the same year in six (26.1%). Only one patient fulfilled criteria for major depression prior to onset of the eating disorder. This distribution is significantly different ($P<0.01$) from equal cell frequencies which are expected by chance. The mean age of onset of anorexia nervosa was 16.3 years (s.d. 4.4), of bulimia 17.9 years (s.d. 3.3), and of major affective disorder 19.8 years (s.d. 4.7). Rates of current DSM-III diagnoses in patients with active anorexia nervosa or bulimia at admission were 25.7% for major affective disorders, 34.3% for anxiety disorders, and 8.6% for substance use disorders. There were no significant differences either in rates of major affective disorder or in rates of anxiety or substance use disorders between the subgroups of eating disorders.

A trend was observed ($P<0.10$) towards a lower rate of major affective disorder in those patients who were interviewed as out-patients one year after hospital treatment and whose eating disorder was in remission. These patients had significantly lower scores in the EDI (MANOVA: $P<0.04$) and the EAT (MANOVA: $P<0.03$) than the in-patients, and only one met DSM-III criteria for major depression at the time of interview.

1. Not using DSM-III exclusion criteria.
2. Number of patients who had at least one diagnosis within the group of disorders.
3. All three patients fulfilled criteria for depressed type of bipolar disorder.

Discussion

Other studies using operational diagnostic criteria have found somewhat higher lifetime rates of major affective disorders in anorexia nervosa (Hudson *et al*, 1983; Herzog, 1984; Piran *et al*, 1985) and in bulimia (Hudson et al, 1983; Walsh *et al*, 1985) than those presented here.

In contrast to previous reports (Hudson *et al*, 1983; Piran *et al*, 1985), the lifetime rate for major affective disorder in patients with anorexia nervosa only was significantly lower than in patients with anorexia plus bulimia, and also lower than in patients with bulimia only. This may be due to differences in duration of illness at the time of interview: the anorexic group differed significantly from the other two groups in this respect. Nevertheless, the data suggest an association of affective disturbance in patients with bulimic symptomatology.

Surprisingly, our sample also yielded high lifetime rates of anxiety disorders, the highest being in patients with bulimia only. These results are consistent with the findings of Hudson *et al* (1983) and other studies reporting a high level of anxiety symptoms, especially in patients with bulimia (Pyle *et al*, 1981).

Lifetime rates of depressive symptoms in our patients were generally comparable with those in patients with major depression. This, in combination with our data on depressive syndromes, leads one to assume that while eating disorder patients experience nearly the whole spectrum of depressive symptoms during their lifetime, half of them do not show enough concurrent symptoms to fulfil DSM-III criteria for major affective disorder.

How can these results be explained? Our finding that nearly half of the patients with eating disorders had displayed lifetime major affective disorder would coincide with the assumption that a substantial proportion of eating disorders might be primary affective disorders (Hudson *et al*, 1983). However, our results on onset of major affective disorder in eating disorders and the low rate of depression at follow-up do not support this hypothesis. Considering studies that have found improvement of depressive symptomatology parallel to improvement of eating disorder (Eckert *et al*, 1982; Fairburn, 1984), we propose a model consisting of several biological and psychological risk-factors for developing a diagnosable depressive syndrome in patients with an eating disorder.

First, specific symptoms (e.g. insomnia, concentration difficulties) which are used to diagnose 'depression' might be directly related to starvation or weight loss (Keys *et al*, 1950; Crisp *et al*, 1971). Secondly, specific abnormal eating behaviour or adaptation to starvation, which is not necessarily dependent on significant weight loss (Pirke *et al*, 1985), may cause changes in neurotransmitter systems that may be responsible for depressive symptoms (Wurtman, 1982). For instance, indications of long-lasting impairment of norepinephrine and serotonin turnover have been described (Kaye *et al*, 1985).

Thirdly, there are three psychological theories of depression that may explain part of depressive symptomatology as a consequence of eating disorder. Patients with long-lasting anorexia nervosa or bulimia usually show marked reduction of social activities (Garfinkel & Garner, 1982; Johnson *et al*, 1984): according to the theory of Lewinsohn (1974), this is related to a significant loss of reinforcers in important life areas and ultimately leads to depression. Anorexic and bulimic patients often feel out of control, ineffective, or helpless (Bruch, 1984; Johnson *et al*, 1984): in many patients those feelings might have been generalised to "learned helplessness" (Seligman, 1975), which is closely related to depressive symptomatology. The third psychological explanation is based on the cognitive theory of depression (Beck, 1976), which assumes that irrational beliefs and cognitive distortions may lead to depression. In fact, such beliefs and distortions have frequently been found in patients with anorexia nervosa (Garner & Bemis, 1982) and bulimia (Fairburn, 1984).

We hold none of these theories alone to be sufficient explanation of major depressive illness in eating disorders, but one might assume that in a substantial subgroup of patients, especially those with bulimic symptoms, these factors interact and lead to depressive symptomatology sufficient to warrant the diagnosis of a major affective disorder according to the DSM-III criteria.

Acknowledgements

The authors would like to thank Dr Heide Hecht and Dr Th. Bronisch for providing the data on the control group. The helpful comments of Dr U. Schweiger and Dr Sabine Bossert are acknowledged.

Prescriptive *v.* Exploratory Psychotherapy

Outcomes of the Sheffield Psychotherapy Project

DAVID A. SHAPIRO and JENNY FIRTH

Prior research suggests that psychotherapeutic techniques which differ in their contents are quite similar in their outcomes. Outcome data are reported from a study designed to maximise sensitivity to technique effects on outcome in a clinically realistic setting, and to permit detailed analysis of the relations between content, immediate impact, and outcome of therapy. Forty professional and managerial workers with depression or anxiety received eight sessions of Prescriptive (cognitive/behavioural) and eight sessions of Exploratory (relationship-oriented) therapy in a crossover design, with each client seeing the same therapist throughout. Outcome was assessed by standard interview and questionnaire methods. The results favoured Prescriptive therapy, although this difference was of moderate extent. The outcome was largely unaffected by the order in which the two methods were offered.

A striking paradox dominates psychotherapy research. On the one hand, practitioners' allegiances to diverse methods are seemingly supported by the results of process research documenting substantial technical diversity among treatments (Strupp, 1955, 1957; Gomes-Schwartz, 1978; Brunink & Schroeder, 1979; Hill *et al*, 1979; Stiles, 1979; DeRubeis *et al*, 1982; Luborsky *et al*, 1982). On the other hand, most major reviews of psychotherapy outcomes have returned the "Dodo bird verdict" (Luborsky *et al*, 1975) that psychotherapy is effective, but that no substantial *differential* effectiveness has been demonstrated (Meltzoff & Kornreich, 1970; Roback, 1971; Smith & Glass, 1977; Smith *et al* 1980; Bergin & Lambert, 1978; Bergin & Suinn, 1975; Beutler, 1979; Frank, 1979). This paradox presents a dilemma: technical diversity despite equivalence of outcomes suggests that therapeutic techniques are irrelevant to outcome (Stiles *et al*, 1986).

Current studies of psychotherapy may be conceptualised in terms of the proposed solutions to this dilemma underlying the various research designs employed (Stiles *et al*, 1986). Within outcome research, the predominant set of solutions attributes the Dodo verdict to poorly conducted outcome research, and advocates increasing the precision with which patient, treatment, and outcome variables are measured and controlled (Paul, 1967; Kazdin, 1980; Rachman & Wilson, 1980). This approach confronts the conflicting requirements of clinical realism *v.* tight control over treatment and extraneous variables. Most of the well-controlled studies are 'analogue research' conducted with non-clinical populations, such as undergraduate students participating in trials of very brief treatments for minor and circumscribed problems, and receiving course credits for their participation (Shapiro & Shapiro, 1983). The art of outcome-research design is the art of compromise (Waskow, 1979). In particular, new ways must be found to approximate in realistic clinical settings the degree of experimental control readily attained in analogue research.

The first substantive issue addressed in the present study concerns the comparative efficacy of dynamic and humanistic therapies *v.* behavioural and cognitive therapies. Meta-analytic reviews of prior research (Smith *et al*, 1980; Shapiro & Shapiro, 1982; Shapiro, 1985) suggest a slight superiority of behavioural and cognitive therapies over dynamic and humanistic therapies, although the latter approaches are clearly at a disadvantage in terms of the quality and quantity of research conducted by proponents. These treatments often appear as quasi-control conditions which the investigators do not expect to be particularly effective, and the behavioural and cognitive orientations of most investigators are a likely source of bias, in view of the correlation obtained by Smith *et al* (1980) between outcome and the allegiance of the investigator inferred from the text of the report. Another limitation is that most of the better designed studies are analogue experiments with clinically unrepresentative samples (Shapiro & Shapiro, 1983).

The conclusions from meta-analysis correspond quite closely to those of the most substantial clinical studies of this comparison with depressed and anxious out-patients. For example, Sloane *et al* (1975) found that neurotic out-patients made similar gains with short-term, analytically oriented psychotherapy and behavioural therapy, with each treatment conducted by experienced practitioners, although ratings of global improvement and of social functioning based on a structured interview slightly favoured the behavioural-therapy group. Klein *et al* (1983) found essentially no difference in the treatment of phobias between behavioural therapy and dynamically oriented, supportive psychotherapy. However, McLean & Hakstian (1979) found greater improvement among depressive out-patients with behavioural therapy than with dynamically oriented psychotherapy, although the dependability of this finding is compromised by sole reliance upon mailed questionnaires.

This pattern of findings suggests that the behavioural and cognitive therapies may enjoy some superiority in the out-patient treatment of depression and anxiety, but that this finding is not unequivocal, and is subject to the qualification that the available data may be somewhat biased against dynamic and humanistic therapies. The Sheffield Psychotherapy Project was therefore designed to ensure maximal control over patient, therapist, and 'non-specific' factors which may account for the variability between previous findings, and to give both treatment approaches an equal chance of demonstrating their efficacy in the treatment of the depressed and/or anxious out-patients who are the primary recipients of psychological treatment.

Our Prescriptive treatment was designed to represent the cognitive and multimodal behavioural therapies (Kanfer & Goldstein, 1975) which emerged from the Shapiro & Shapiro (1982) meta-analysis of outcome research as particularly promising. This method incorporates anxiety-control training (Snaith, 1974), self-management (Goldfried & Merbaum, 1973), cognitive restructuring (Meichenbaum, 1977; Beck *et al*, 1980) and a work-oriented package derived from management-training literature to suit professional and managerial employees (Hackman & Suttle, 1977; Taylor, 1979; Ferner, 1980).

The dynamic and humanistic therapies are represented by Exploratory therapy, based upon Hobson's (1985) Conversational Model. This method synthesises interpersonal and client-centred concepts and focuses upon the use of the therapeutic relationship as a vehicle for the revelation and resolution of interpersonal difficulties and conflicts. Prior research (Goldberg *et al*, 1984; Maguire *et al*, 1984) has specified constituent techniques within this method, and shown that these can be taught to psychiatrists in training. A videotape microteaching package and brief manual are available (Margison & Hobson, 1983).

Our objectives in designing this study were to maximise its sensitivity to treatment effects and permit high-power examination of correlations between process, impact, and outcome variables (to be reported subsequently). We selected a cross-over design with each patient seen by the same experienced therapist in both periods, to maximise control over patient and therapist variables. Since our primary interest was in comparing the processes and outcomes of different therapies, and in view of evidence for the overall efficacy of psychological treatments (Smith *et al*, 1980) and the logistic and ethical difficulties associated with placebo or no-treatment controls in a realistic clinical setting, no such control groups were employed.

A second substantive question addressed by this study concerned sequence effects within eclectic therapy. Several authors have described the complementary use of behavioural and psychodynamic therapies (Birk & Brinkley-Birk, 1974; Wachtel, 1977; Birk, 1979; Bernstein, 1984). Most authors have used one treatment adventitiously when progress in the other appears impeded in some way (Brady, 1968), but it has been argued (Luborsky, 1984) that purity of modality is an essential feature of eclectic therapy; that is, one type of treatment should be completed and then followed by another according to plan, rather than the therapist being allowed to respond to day-to-day expressions of client needs, which can permit avoidance of difficult issues.

If eclectic treatment packages are to be constructed along these lines, the question arises as to which therapy should be offered first. When behavioural techniques precede psychodynamic, this may allow behavioural work to deal with immediate crises prior to psychodynamic exploration of the interpersonal issues which may have originally precipitated the crisis (Bernstein, 1984), or behavioural techniques may be used to bring into the open anxieties or conflicts and thereby facilitate the psychodynamic work which follows (Levin *et al*, 1968). Conversely, brief psychodynamic work may be usefully followed by practice and rehearsal of new adaptive techniques and their generalisation (Marmor, 1979).

In this context, it is of interest to use a cross-over design to address the question of which of the two orders, Exploratory followed by Prescriptive or Prescriptive followed by Exploratory, is the more effective.

Method

Measures

Our approach to outcome assessment was based upon the recommendations of the National Institute of Mental

Health review of psychotherapy change measures (Waskow & Parloff, 1975), adapted to reflect prevailing practice in the UK. Measures used included substantial interviews assessing psychiatric symptomatology and social role performance, the Present State Examination (PSE; Wing *et al*, 1974), and the Social Adjustment Scale (SAS; Weissman & Paykel, 1974); and four self-report questionnaires: the Beck Depression Inventory (BDI: Beck *et al*, 1961), a standard symptom checklist, the SCL–90 (Derogatis *et al*, 1973) and the O'Malley & Bachman (1979) eight-item revision of the Rosenberg (1965) self-esteem scale, presented in a seven-point format (SE). The PSE yielded a total symptom score suitable for parametric analysis, obtained by summing the scores obtained for each item. The Index of Definition (Wing *et al*, 1974) was obtained from the ID-CATEGO program at the Institute of Psychiatry. The SAS was represented by the grand mean of all items on every scale. On each occasion, patients were asked to consider the month prior to assessment when responding to the PSE and SAS questions. At intake, all patients were required to score at least 8 on the 30-item version of the General Health Questionnaire (GHQ; Goldberg, 1972), and to attain a total symptom score of at least 14 on the PSE, although those with obsessional or psychotic symptoms on the latter instrument were excluded as unsuitable for brief, out-patient psychotherapy.

Recruitment of patients

Patients were referred by general practitioners, psychiatrists, and company doctors, who were posted information publicising our specialist clinic offering psychological therapy to professional and managerial workers suffering from depression and/or anxiety. Many patients, eventually referred by general practitioners, made their initial contact with our clinic in response to publicity materials distributed in appropriate employment settings by welfare and personnel staff. Initial screening criteria excluded people not complaining that their work was affected by their problems, those with a continuous history of psychiatric disorder extending more than two years prior to the time of referral, and those who had during that period undergone psychological treatment sufficiently similar to pre-empt either of our two treatment modalities. We also excluded those who had undergone a significant change in psychotropic medication during the three months prior to referral. Such significant changes included commencing or finishing a course of treatment, or switching from one type of medication to another (such as from benzodiazepines to antidepressants).

Potential patients were mailed the GHQ and SCL–90. On receipt of the completed questionnaires, the intake assessment was scheduled with a research assistant, who administered the PSE and SAS, together with questionnaires including BDI and SE. Patients were excluded at this stage when interviews revealed psychotic or obsessional symptoms sufficiently severe to be scored 1 or more on the PSE, or insufficient PSE symptomatology (total score below 14). The objectives and requirements of the research programme were set out in a three-page outline handed to accepted patients after the intake assessment. This presented the goals of the project as being to "find out more about which of two well-established methods is more helpful to what kinds of people", and covered the structuring of treatment into two distinct phases, the audio-recording of all sessions, and the completion of impact and outcome measures.

In all, 108 individuals were referred to or approached the clinic during the period of recruitment to the study. Of these, 75 completed the GHQ and SCL–90, and 55 attended for intake assessment. Forty-eight were randomised, having met the inclusion criteria. Two of these (one assigned to each order of treatments) decided against therapy. A further six (three assigned to each order) failed to complete treatment, four terminating during Prescriptive and two during Exploratory therapy. Three of these six completed one eight-session phase of treatment and showed typical gains over that phase, but did not wish to continue treatment after 1–5 sessions of the second phase. The remaining three discontinued after 3–6 sessions of the first phase; these patients did not appear to form a commitment to therapy. The present analyses concern 40 patients completing therapy, whose mean age was 40.7 years (s.d. 8.4 years).

Intake and outcome assessments

There were four assessments: intake, mid-therapy (between the two treatment phases), end of therapy, and a three-month follow-up. Interviews were conducted by social science graduates who had undergone training in the PSE and SAS. The BDI, SCL–90 and SE were administered in a single package by the interviewer, except that the intake SCL–90 scores were based on the mailed questionnaire. In most cases, patients were interviewed by the same research assistant at each of their four assessments. Where this was not possible, data were based upon ratings of all four assessments by the same interviewer (who listened to tapes of assessments carried out by her colleague), so as to reduce error due to variations between assessors. Assessors were not informed of the order in which each patient was assigned to treatment.

Patients were informed by both assessor and therapist that outcome data were not made available to the therapist until after the completion of treatment. All patients were offered a single consultation with their therapist after the follow-up assessment, at which their progress could be reviewed and they could receive advice concerning the appropriateness and availability of further treatment.

Assignment to therapist and order of treatment

Patients were assigned to therapists in accordance with scheduling and workload constraints. As far as practicable, we balanced the numbers of each sex seen by each therapist. Other commitments entailed that 34 patients be shared equally between the two authors, with the other two therapists contributing four and two patients. All therapists were full-time research clinical psychologists, selected for an eclectic orientation valuing both treatment modalities. Their initial professional training (at UK master's level) represents a level of experience intermediate between master's and doctoral levels in the USA. At the outset of the project, the first author had ten years' post-doctoral research and clinical experience. The second author began pilot work for the project upon completion of her master's training, and had had experience in counselling prior to that training. The other two project therapists had some three years' clinical experience and training in psychotherapy after their initial professional training. All therapists had been trained in both behavioural and relationship-oriented therapies prior to taking part in the study.

Assignment to order of the two treatments was determined by the toss of a coin for each alternate patient of a given sex assigned to each therapist, with the next patient of that sex seen by that therapist automatically assigned to the reverse order. This procedure counterbalanced any maturational changes in therapist behaviours over the course of the study. An assignment error by the first author resulted in an imbalance between the groups; 19 patients received Exploratory therapy first, and 21 received Prescriptive therapy first.

Scheduling of treatment and assessment sessions

Treatment began approximately three weeks after the intake assessment. Each treatment phase comprised eight weekly 1-h sessions. The mid-treatment assessment occurred 1-3 weeks after the eighth treatment session, and the second phase of treatment began 1-3 weeks later. The post-treatment assessment was scheduled 1-3 weeks after the last session, and the follow-up assessment three months later.

Treatments

The design of each treatment in the form of an eight-session package was evolved in preliminary pilot work, in the context of a review of the above-cited clinical texts. Fifteen-page manuals were written to define the objectives, strategy and techniques of each treatment. A summary of the contents of each follows.

Prescriptive therapy. This treatment emphasises the provision by the therapist of self-management strategies for application by the patient. The focus of therapy is upon the patient's behaviour outside the sessions. A wide range of techniques is outlined in the manual, divided into four areas: (a) anxiety-control training, including relaxation, anxiety management and graded exposure to anxiety-provoking situations both in imagination and *in vivo*; (b) self-management procedures, including contracting, behavioural tasks, guidance on changing the environment (e.g. via timetabling), self-monitoring (e.g. via diaries), and assertion training; (c) cognitive restructuring, including systematic rational restructuring, engendering more realistic goals and norms, engendering expectations of controllability, and challenging dysfunctional attributions; (d) a job-strain package, including analysis and reduction of friction at work, cognitive and thought-stopping methods of countering worry, time management and cognitive restructuring of work attitudes, delegation training, and functional analysis and remediation of concentration and memory problems. With each patient, elements are drawn from each of the four areas; there is no expectation that every technique can be included within eight sessions. Maintenance strategies are emphasised throughout, with the explicit rationale that therapy provides the patient with resources which he or she must continue to apply and develop after the completion of treatment.

Exploratory therapy. Key features of this treatment include the following: (a) the assumption that the patient's presenting problems arise from disturbances of significant personal relationships; (b) the creation within the therapy situation itself of a relationship in which the patient's interpersonal problems are revealed, explored, understood and modified by the testing-out of possible solutions which are generated in the dialogue (this contrasts with the prescriptive treatment's assumption that the therapeutic relationship is primarily a vehicle for the transmission from therapist to patient of knowledge, skills and principles to assist the patient in his life outside therapy); (c) the adoption by the therapist of conversational strategies designed to promote the process defined in (b) above, including *negotiation*, a language of *mutuality*, the use of *metaphor* to enhance the immediacy and 'wholeness' of experienced affect, *focusing* on the here and now experience of the patient in the interview, and the offering of *hypotheses* ranging from *understanding* hypotheses expressing the therapist's view of the patient's experience, through *linking* hypotheses suggesting connections between different experiences of the patient's, to *explanatory* hypotheses suggesting causes or reasons for behaviour and experience; (d) emphasis upon interpersonal problems arising within professional and managerial employment. In relation to maintenance, the explicit rationale of this method is to furnish links between the therapeutic relationship and other relationships so that insights and new solutions to interpersonal problems will generalise outwards from therapy.

Implementation

Therapy took place within our research clinic, in a city-centre university setting. The project therapists met at least once weekly for peer supervision, with every case presented after the second session within each of the two treatment modalities. Expert practitioners of the two modes took part in a total of some 60 supervision sessions during the course of the study. The work of the supervision sessions was directed toward the delivery of clinically representative and effective therapy, as well as to the maintenance of therapists' adherence to the treatment manuals. Audio recordings were made of every session for research and supervision purposes. Therapists made process notes for each session, using forms designed for the two treatment modalities. These notes were taken during the Prescriptive sessions, and after each Exploratory session.

At the first treatment session, the therapist reminded the patient of the research requirements, particularly of the structuring of treatment into two distinct phases, and outlined once more the rationales of the two methods. Although the great majority of problems were tackled in both phases, therapists were during the first phase at liberty explicitly to defer work distinctly appropriate to the second phase. Efforts were also made to shape the first phase as a distinct entity with goals to be attained within the eight-session span. Thus, as the eighth session approached, there was an increasing emphasis upon maintenance strategies in Prescriptive therapy and upon termination work in Exploratory therapy (expressed in terms of the loss of the therapeutic relationship). Particular attention was paid to the negotiation of the transition between treatment modalities. The final session of treatment necessarily involved some review of the work of both treatment modalities. We present elsewhere a discussion of these and other aspects of the implementation of the study design from a practitioner's perspective (Firth *et al*, 1986).

Manipulation check

Adherence to the treatment protocols was confirmed via a manipulation check of the verbal-response mode usage of therapists (Shapiro *et al*, 1984) in the two treatments. These data, reported fully elsewhere (Hardy & Shapiro, 1985), show substantial and predicted differences in the interpersonal intents or functions of therapist utterances as between the two treatment modalities. Excerpts selected at random from the treatment of patients included in the present study revealed greater use of interpretation, exploration, and process advice during exploratory therapy, and greater use of question, information, and general advisement during prescriptive therapy. Despite the control for individual therapist factors secured by the use of the same therapist in both treatments with each patient, differences in the percentage of therapist responses in a given category ranged from more than twofold to over sixfold.

Results

Initial comparability of groups

Table I shows the means and standard deviations obtained on each outcome measure at each of the four assessments. For SCL-90 and SE, the groups were essentially equivalent at intake ($t<1$ in each case). In terms of the PSE Index of Definition (ID) at intake, all but one patient in each group was at the 'threshold' level of caseness ($\mathrm{ID}=5$) or above. Despite random assignment, however, the Exploratory–Prescriptive (EP) group was somewhat more disturbed at intake on the SAS ($t(38)=2.07$, $P<0.05$) and marginally more symptomatic on the PSE ($t(38)=1.67$, $P=0.10$) and BDI ($t(38)=1.43$, $P=0.16$). The two groups were of similar age ($t(38)<1$). The EP group comprised 11 males and 8 females, while the Prescriptive–Exploratory (PE) group comprised 12 males and 9 females. Educationally, the EP group comprised 10 with university or college education, 4 with professional or other post-school qualifications, and 5 with no such qualifications; the PE group comprised 13 with university or college education, 2 with professional or other post-school qualifications, and 6 with no such qualifications. In terms of jobs held, the EP group comprised 4 teachers, 6 managerial/financial workers, 6 helping professionals, 2 technical/engineering workers, and 1 civil servant; the PE group comprised 7 teachers, 5 managerial/financial workers, 4 helping professionals, 2 technical/engineering workers, and 3 civil servants.

Clinical severity at intake and clinical significance of change

Table I shows that, at intake, this was a population with mean levels of symptomatology and distress well into the clinical range of severity. In terms of PSE ID level, 7 patients were clear 'cases' ($\mathrm{ID}=6$) and 31 were at the 'case threshold' ($\mathrm{ID}=5$). Social adjustment appeared less severely disturbed, however, reflecting the restriction to those currently employed in professional and managerial jobs. The most rigorous of the criteria discussed by Jacobson *et al* (1984) for the evaluation of the clinical significance of change occurring in psychotherapy research studies is based on the proportion of patients attaining end-of-treatment scores two or more standard deviations beyond the intake mean. The implication of such end-of-treatment scores is that individuals attaining them cannot be reasonably viewed as members of the intake population, irrespective of the degree of elevation of that population's

[1] Recovery is defined as two or more standard deviations beyond pretreatment mean.

scores relative to a normal population. Table II shows the percentages of patients meeting this criterion of recovery on each measure at mid-treatment, end of treatment, and follow-up. On this demanding criterion, around half the patients improved on the symptomatic measures (PSE, BDI and SCL–90), somewhat fewer improved on the SAS, but few changed with respect to self-esteem. In terms of PSE 'caseness', by the end of treatment only 12 patients were at the threshold (ID = 5) and none was above this value. Follow-up data showed essentially no change from end of treatment.

Analysis of treatment effects

To evaluate the differential effects of treatments and of their order upon outcome in the context of the above-described differences between the two groups at intake, two alternative methods of analysis were employed. Residual gain scores, from which the effects of each individual's intake score are statistically removed, are often favoured (e.g. Cronbach & Furby, 1970; Mintz *et al*, 1979). However, residual gain scores only correct for initial differences to the extent permitted by the size of the correlation between scores obtained at the different assessments. In the present data, correlations between intake and mid-treatment scores ranged from 0.32 for the BDI to 0.61 for the SE measure; correlations between mid-treatment and end-of-treatment scores ranged from 0.39 for the BDI to 0.80 for the SAS; correlations between intake and end-of-treatment scores ranged from 0.20 for the SCL–90 to 0.46 for the SAS; and correlations between intake and follow-up scores ranged from 0.14 for the SCL–90 to 0.39 for the SAS. The modest size of most of these correlations suggested that simple change scores, which by definition correct fully for the effects of earlier measures, should be considered alongside residual gain scores. All analyses of treatment effects were therefore performed twice, using both residual gain and simple change (arithmetic difference) scores.

The combination of data from the two periods of a cross-over design is legitimate only in the absence of interaction between treatment and period (Hills & Armitage, 1979; Armitage & Hills, 1982). Such an interaction is identical with the between-groups difference in change over the two periods combined (from intake to end of treatment). This between-groups difference was also of interest in relation to our examination of order effects in eclectic therapy. The first step in the analysis of each outcome measure, therefore, was the comparison of residual gain scores for the two groups, comprising the end-of-treatment scores expressed as residuals from the values predicted from the intake scores. The parallel analysis of simple change scores compared end-of-treatment minus intake scores in the two groups.

As a longer-term test of the effect of the order of treatments upon outcome, residual gain scores comprising the follow-up data expressed as residuals from the values predicted from intake scores were compared for the two groups of patients. Similarly, simple change scores comprising follow-up minus intake scores were compared in the two groups.

Changes occurring during the two treatments were compared for each period separately, using residual gain scores comprising the mid-treatment values adjusted for intake scores to represent change during the first period, and residual gain scores comprising the end-of-treatment values adjusted for mid-treatment scores to represent the second period. Similarly, simple change scores comprising mid-treatment minus intake scores, and end-of-treatment minus mid-treatment scores, were compared to assess change in each treatment for each period in turn.

Before combining the two periods of the cross-over, a liberal significance level of 0.10 was set for rejection of the null hypothesis of no interaction between treatment and period. In the absence of interaction in the residual gain scores, residual gain scores for both periods (with mid-treatment scores controlled for intake scores and end-of-treatment scores controlled for mid-treatment scores) were analysed following the ANOVA method of Hills & Armitage (1979). In the absence of interaction in simple change scores, these were analysed similarly.

Effect of treatment order on end-of-treatment scores

Analysis of residual gain scores based on the end-of-treatment scores expressed as residuals from the values predicted from intake scores revealed no difference in overall change between patients assigned to the two orders of treatment. With respect to the BDI, SCL–90, SAS, and SE measures, the t value for this comparison was less than 1. The remaining measure, the PSE, also showed no significant difference between the groups ($t(37) = 1.13$, $P > 0.25$). In the analysis of simple change scores, the PSE, SCL–90, and SE scale yielded t values less than 1. The BDI and SAS yielded t values of 1.40 ($P = 0.17$) and 1.17 ($P = 0.25$) respectively. Of the ten comparisons yielded by the five measures and two methods of analysis, the arithmetic values of six favoured the EP group and four the PE group. These findings show an absence of interactions between treatment and period indicative of carryover effects. It was therefore appropriate to test for treatment effects over both periods of the study via within-subjects analysis of the crossover for all five outcome measures, and for both residual gain and change scores.

Effect of treatment order on follow-up scores

Analysis of residual gain scores comprising the follow-up scores expressed as residuals from the values predicted from intake scores revealed no difference in

TABLE III
Residual gains during Prescriptive and Exploratory therapies

Period	*Treatment*	*Measure*				
		PSE	*BDI*	*SCL–90*	*SAS*	*SE*
First	Prescriptive	1.70	1.86	12.64	0.04	1.30
	Exploratory	−1.88	−2.05	−13.98	−0.05	−1.44
	t	2.35**	1.90*	2.62**	1.04	1.08
Second	Prescriptive	−0.20	0.68	9.17	0.03	1.56
	Exploratory	0.17	−0.55	−7.43	−0.03	−1.33
	t	<1	<1	1.53	<1	1.32
Combined	t	1.35	1.97*	2.41**	1.38	1.75*

$^{*}P<0.10$; $^{**}P<0.05$; $^{***}P<0.01$.

overall change from intake to follow-up between patients assigned to the two treatment orders with respect to the PSE, BDI, SAS, or SE measures ($t<1$ in each case). For the SCL–90, however, there was a non-significant trend towards greater improvement at follow-up for the EP group ($M=9.47$) than for the PE group ($M=-8.12$; $t(37)=1.51$, $P=0.14$). In the analysis of change scores from intake to follow-up, the PSE, SAS, and SE all yielded t values less than 1, while the BDI and SCL–90 both yielded non-significant advantages to the EP group, with t values of 1.38 ($P=0.17$) and 1.51 ($P=0.14$) respectively. The arithmetic values obtained for seven of the ten comparisons favoured the EP over the PE group. Notwithstanding these non-significant trends in favour of the Exploratory–Prescriptive order, both end-of-treatment and follow-up results suggest that an eclectic package combining Prescriptive and Exploratory therapies is almost equally effective irrespective of the order in which the two treatments are offered.

Comparative outcomes of Prescriptive and Exploratory therapies

Table III shows the mean residual gains made by patients undergoing each treatment in each period of the study, together with the means of the two periods for each treatment. By definition, the mean residual gain across all 40 patients on any measure for either period is equal to zero; a positive value in Table III denotes a group whose scores at the end of the relevant period of treatment are more favourable than would be predicted from knowledge of their scores at the beginning of that period, while a negative value denotes scores less favourable than so predicted. The difference between each pair of means was evaluated by a t-test, the results of which are also presented in Table III. The within-subjects analysis of the two periods combined is represented by the final row of t values in the table. The pattern of these data clearly favours Prescriptive therapy, whose residual gains were positive in all but one of the ten comparisons. In the first period, gains were significantly greater for Prescriptive therapy on the PSE and SCL–90, and marginally greater on the BDI, although no treatment effects were significant in the second period. Data for the two periods combined indicated a significant advantage to Prescriptive therapy on the SCL–90, accompanied by marginally significant differences in the same direction on the BDI and SE measures.

The corresponding analysis of simple change scores is presented in Table IV. For each measure, a larger score means greater improvement. All ten comparisons show

TABLE IV
Change scores during Prescriptive and Exploratory therapies

Period	*Treatment*	*Measure*				
		PSE	*BDI*	*SCL–90*	*SAS*	*SE*
First	Prescriptive	9.38	9.67	55.19	0.31	6.33
	Exploratory	7.05	7.79	34.64	0.28	4.32
	t	1.32	<1	1.56	<1	<1
Second	Prescriptive	3.72	6.00	40.71	0.29	8.65
	Exploratory	2.05	1.09	10.81	0.14	4.40
	t	<1	2.26**	2.67**	2.11**	1.72
Combined	t	1.36	1.68*	2.76***	1.40	1.50

$^{*}P<0.10$; $^{**}P<0.05$; $^{***}P<0.01$.

arithmetic differences in favour of Prescriptive therapy, which attain significance during the second period of the study for the BDI, SCL-90 and SAS. The within-subjects analysis of effects for the two periods combined shows a significant advantage to Prescriptive therapy on the SCL-90, and a marginally significant difference in the same direction on the BDI. Although residual gain scores suggest stronger effects in the first period, while simple change scores do so only in the second, the results presented in Tables III and IV show a consistent difference in favour of the Prescriptive treatment.

In view of the similarly high proportion of patients in the two groups who were at or above the threshold of psychiatric caseness at intake, an additional measure of treatment effect was obtainable from the proportions of patients in each group who remained cases (ID = 5 or 6) at mid-treatment. Nine patients were still cases after exploratory therapy, while seven were still cases after prescriptive therapy; this difference was not statistically significant (chi-square < 1). A similar analysis of change during the second period was equally inconclusive: seven of the PE group, and five of the EP group, were threshold cases at the end of treatment.

Discussion

Before considering the answers to our substantive questions suggested by these results, it is worth noting the absolute magnitude of change observed during therapy. As shown in Tables I and II, this was at intake a clinically distressed sample, and large changes occurred, particularly on the symptomatic measures. For example, around 11 PSE symptoms were lost by the average patient in the study. Many patients made sufficient gains to be deemed 'recovered' (i.e. outside the range of intake scores) by the end of treatment. In terms of the PSE ID criterion, nearly all the patients were at or above threshold at the outset of treatment, but only a quarter remained so after treatment. These gains were maintained at three-month follow-up. Although these absolute changes reflect non-specific factors and 'spontaneous' change in addition to effects attributable to specific treatment techniques, they suggest that 'real' therapy was taking place, despite research constraints (Firth *et al*, 1986).

Overall, our findings suggest that Prescriptive therapy was somewhat more effective than Exploratory. This difference was most consistent and substantial over the study as a whole for the SCL-90, where more than twice as much improvement was observed during Prescriptive than during Exploratory therapy. Analysis of residual gains on the PSE and BDI showed greater reduction of psychiatric symptoms in Prescriptive than in Exploratory therapy during the first period of the cross-over, while simple change scores on these measures were greater during Prescriptive than Exploratory therapy during the second period of the study. The two remaining outcome measures (SAS and SE) showed trends in the direction of greater efficacy for Prescriptive therapy.

These results are evidence against the view that all therapies have equivalent outcomes. They are consistent with the suggestion that findings of equivalent outcomes may be due to poor control over those extraneous therapist, technique, and patient variables which were well controlled by our design. This control was achieved by the use of the cross-over design with the same therapist for each patient throughout; the manualisation, weekly peer supervision and monitoring of technique; and the socioeconomic homogeneity of our patient population. All these design features enhanced the study's sensitivity to treatment differences.

On the other hand, our findings as a whole do not imply a massive difference between the treatments. The PSE data, for example, show a difference around 2 points, equivalent to two symptoms falling from marked (2) to moderate (1) or dropping below the level required for a rating of 1, in the context of the 11-point overall improvement during treatment. The clinically meaningful caseness criterion of the PSE ID did not differentiate the two treatments. BDI changes differed by about 3 points, while overall changes during treatment averaged around 12 points. Even allowing for maturational and non-specific contributions to the substantial overall changes, these data attest only to a modest treatment effect, particularly in view of the study's sensitivity to it.

Advocates of Exploratory therapy could argue that our design was disadvantageous to that treatment. Eight sessions may be too few for this method to be effective, with existing defences unsettled but too little time in which to establish new ways of coping. In addition, it is possible that a delayed measure of effectiveness, unconfounded with any alternate treatment, would be more favourable to Exploratory therapy. The measures used may be insufficiently sensitive to intrapsychic change, although it is noteworthy that even SE data tended to favour Prescriptive therapy. On the other hand, any investigator bias was more likely toward rather than against Exploratory therapy, given our research team's concern to redress the balance of opinion within a national professional culture which tends to favour behavioural over non-behavioural methods (Shapiro & Shapiro, 1977).

With respect to the ordering of treatments within an eclectic package, our findings comparing the gains made by patients receiving the two treatments in different orders were almost uniformly equivocal.

Of 20 tests of this order effect, none attained statistical significance, and 13 yielded arithmetic values favouring the EP order, as against 7 favouring the PE order. Overall, these data do not support one ordering as more favourable than the other.

Although these findings can be usefully viewed as complementary to previous studies suggesting that cognitive and behavioural therapies may be a little more effective than are dynamic and humanistic treatments, it would be inappropriate to generalise from the present comparison between two specific treatment models to all treatments within these two broad classes.

Our two parallel analyses, of residual gain scores and of simple change scores, yielded findings which differed in detail but were consistent in favouring Prescriptive over Exploratory therapy. As far as residual gain scores are concerned, the treatment differences at mid-treatment are presumably in part a reflection of the intake differences, which were incompletely controlled by the residualising procedure, given the modest correlations between measures obtained at successive outcome assessments. On the other hand, no such reservation qualifies the interpretation of the treatment effects on simple change scores during the second period of the study.

In the light of the findings obtained, the choice of a cross-over design may be seen to have somewhat enhanced the study's detection of treatment effects. The inclusion of the second period, in which patients received the alternate treatment, allowed detection of a significant treatment effect on the SAS, and confirmation of an effect on the BDI which was only marginally significant during the first period. Furthermore, the effects of treatment order within the combined eclectic package can only be ascertained by such a design.

In addition, a cross-over design makes available invaluable process data in which patients are their own controls. Although this paper has focused exclusively upon the outcomes of our two treatments, presenting the project as a 'horse race' between them, the full benefits of our research strategy will be realised when these outcome data are linked with further measures concurrently obtained on these patients, including verbal response modes utilised during sessions by therapists and patients (Stiles & Sultan, 1979; Stiles, 1984), evaluations of the immediate impact of each session (Llewelyn & Hume, 1979; Stiles, 1980; Elliott *et al*, 1985), and week-to-week changes in self-rated target problems (Mulhall, 1976). To the extent that our outcome findings imply differential effectiveness of the two treatments, these process measures will contribute to our search for active ingredients to account for this difference. Process analyses will also permit evaluation of contrasting mechanisms of change postulated for the two treatments, whereby divergent pathways may lead to comparable final outcomes.

Acknowledgements

We gratefully acknowledge clinical supervision by Robert F. Hobson and Ian Burnside, participation as therapists by Gillian Hardy and Glenys Parry, interviewing and data processing by Lisa Davies, Ann Macaskill, Brenda McWilliams and Leslie Morrison, administration of our clinic by Mary Lou Hughes, training in the Present State Examination by Paul Bebbington and Traolach Brugha, help with the Social Adjustment Scale by Eugene Paykel, and support and advice from Robert Elliott, Bill Stiles, and Social and Applied Psychology Unit colleagues.

Explaining and Understanding in Psychopathology

KLAUS P. EBMEIER

Psychoanalytical methodology has been described as causal explanation or hermeneutic understanding. This methodological dichotomy has been introduced into psychopathology by Karl Jaspers. Contemporary authors' contributions in the area are discussed. Although these authors accept a role for both methods, they agree with Jaspers that psychoanalysis should be subjected to the logical limitations of hermeneutic analysis. A logical framework for the interaction of explaining with understanding is presented and discussed in relation to psychiatric research.

In a recent critical analysis, Gellner (1985) suggested that a "biohermeneutic fusion" of concepts – that is, the conflation of meaningful and causal connections (see below) – has helped psychoanalysis to assert and maintain its role as a healing discipline. Understanding meaningful connections by itself, he argues, is not sufficient to capture the imagination of the sufferers. After all, meanings can be found without professional help. A purely biological theory, on the other hand, demeans man by reducing him to a "bundle of animal drives". Mixing both elements gives meanings increased depth and authority (by virtue of being linked to biological forces) and helps patients to retain their dignity in the face of biological determinism (thanks to the meaning which has to be analysed on a personal level). Thus, "bio-hermeneutics is simultaneously reductive (thereby giving control) and restorative (dignity-preserving)" (Gellner, 1985).

The interplay of causes and meanings, or explaining and understanding, in psychoanalysis has been noted earlier: the first discussion of psychoanalytic methodology under these headings was carried out by Karl Jaspers in his *General Psychopathology* (Jaspers, 1963).

This paper will examine some of the limitations of explaining and understanding, as conceived by Jaspers, as methods of psychopathological investigation. Contemporary definitions of psychoanalysis as a discipline which uses both explaining *and* understanding will be discussed in an attempt to define the methodological constraints imposed upon psychoanalytic theory and practice. A logical framework for the interaction of both methods in psychopathology will be proposed.

Jaspers: Psychoanalysis is an hermeneutic discipline mistaking itself for a causal science

Jaspers' concept of *causal analysis* is derived from Hume's (1962) regularity model of causality: the discovery of regular temporal conjunctions between two kinds of events leads to the postulation of a general law, which *explains* this conjunction. The general law, in turn, can be used to predict future conjunctions of events of the same kind.

Empathic understanding is a method modelled by Jaspers on the hermeneutic disciplines, philology and history. *Hermeneutics* (literally, the art of interpretation) always starts with a preliminary understanding. A facial expression with closed eyes and tears rolling down the cheeks is recognised as crying. This momentary facial expression, however, can have many, sometimes contradictory, meanings. It makes a difference whether someone has just received news of the death of a close relative, has been told a joke, or has been peeling onions; an examination of the context of the expression is necessary to define it more precisely. Knowing that a patient has a hysterical personality shows the crying in a different light than would the detection of organic brain disease, like pseudo-bulbar palsy. Conversely, the context is modified by appreciation of the detail. For example, crocodile tears which can be wiped away as soon as their purpose is achieved might point towards a particular kind of personality.

Hermeneutic analysis, therefore, follows a movement rather like ascending a spiral staircase. The preliminary understanding is modified by a successive appreciation and reappreciation of details and context. If new observational material is gathered at each stage, an infertile circle is avoided, and more and more precise understanding can be achieved. This procession from the part to the whole and back can never be complete. Understanding can, therefore, never be final. Consequently, contrary interpretations are often equally plausible. One can understand how a handicap could lead to withdrawal from competition, but one can equally understand that a handicapped person might try to make up for disadvantages by developing his remaining capabilities and skills even to the degree of surpassing his healthy peers. Although meaningful connections can be found in the analysis of human expressions and artifacts, understanding has its limits: one cannot *understand* empathically why a patient with pseudo-bulbar palsy cries or laughs. The finding that other patients with similar brain lesions show the same behaviour, offers a causal *explanation*.

It follows that both explaining and understanding are applicable in the human sciences. Where understanding ends, explanations are still possible, and where understanding is possible using objective data this might point towards a causal connection. In order to establish a causal law, however, external data will have to be adduced to avoid circular arguments. Violent behaviour cannot be explained in terms of an explosive personality if this personality is diagnosed by the observation of just this violent behaviour. An observation external to the process of understanding is necessary for a causal explanation, as for example the detection of EEG abnormalities in this kind of personality disorder (Williams, 1969).

Understanding by means of conjectured mechanisms like the ego, the unconscious, or libido, is, in Jaspers' terminology, 'as if' understanding. These mechanisms have to be postulated in order to explain non-understandable observations like conversion symptoms or dissociative states. They lack, however, externality and independence from the process of empathic understanding and, therefore, lead to circular rather than causal statements (Nagel, 1959). Jaspers comes to the conclusion that psychoanalysis is an understanding psychology, which frequently uses 'as if' understanding, but is presented by Freud as a causal science similar to the natural sciences.

Explaining and understanding in contemporary descriptions of psychoanalysis

More recently, psychoanalysis has been described as either a causal science (Hartmann, 1964; Rubinstein, 1973) or as a hermeneutic discipline (Rycroft, 1966; Lacan, 1977). Other authors have commented on the interaction between explaining and understanding in psychoanalytic theory and practice. Three of the latter, Ricoeur, Habermas, and Bhaskar, will now be discussed in more detail.

Jaspers argued for a total disjunction between causal and meaningful connections in psychopathology (Jaspers, 1963), which led to his definition of psychoanalysis as a hermeneutic discipline. Ricoeur's refusal to accept this disjunction becomes the basis of his interpretation of Freudian theory (Ricoeur, 1970). He identifies two elements in Freudian theory: libido theory, which uses dynamic explanations, modelled on a physical theory of hydraulics; and the interpretation of dreams, parapraxes, and the like. Ricoeur's central question is how a dynamic explanation can be involved in an interpretation dealing with meanings, and conversely, how an interpretation can be an aspect of a dynamic explanation. If psychoanalysis was made an operational science like academic psychology, it would lose its distinctive character as an interpretative enterprise dealing with the symbolic relationships between substitute objects and the primordial (and lost) instinctual objects. On the other hand, the understanding of human motives alone is unable to account for Freudian concepts like cathexis, where the language of intention and meaning is replaced by energy metaphors. A distortion between literal and intended meaning evokes mechanisms like dreamwork, displacement and condensation. Jaspers' verdict that these mechanisms only promote 'as if' understanding is judged to be too harsh, because their reality is deducible from the manifestation of object relations, which reappear and can be examined in the transference relationship.

The weakness of Ricoeur's argument lies in his acceptance of Freud's dynamic mechanisms. Even if one accepted that these mechanisms correctly took over where empathic understanding was at an end, and that they were providing a plausible and coherent explanation of the observed phenomena, Jaspers' criticism of 'as if' understanding still holds. Psychodynamic mechanisms, as long as they are only based on the *failure to understand* a patient's behaviour by examining all overt clues, are circular and fanciful constructs. In order to become valid explanatory constructs they must be identifiable independently of the psychotherapeutic dialogue (Nagel, 1959).

Habermas, a contemporary representative of the Frankfurt School of Critical Theory, has developed a theory of knowledge in which psychoanalysis occupies a special place (Habermas, 1978). He acknowledges the difference in methods between causal sciences and hermeneutic disciplines, but gives it a novel meaning. Categories like space, time, substance, and causality are, according to Kant (1931), implied with the perception of any object, independently of its particular impression on our senses. In a similar fashion Habermas postulates constitutive interests in knowledge which underlie scientific activities. He recognises a technical interest to manipulate and predict the environment. Its method is causal analysis, and its field, the natural sciences. Similarly, the interest of interpersonal communication underlies the understanding of meaningful connections in the human sciences. Habermas criticises the extension of the technical interest into the human sciences: sociology and psychology, whenever they try to establish laws in order to predict human behaviour, introduce an unjustified sense of necessity. They tend to maintain the status quo, and can act as 'false consciousness' or ideology that prevents the emancipation of human beings or groups.

Habermas takes Freud's statement, "where there was Id, there shall be Ego", and defines the task of psychoanalysis as the shifting of the barrier between explaining and understanding by self-reflection. Seemingly unavoidable acts like compulsions or conversion symptoms are brought back into the realm of intentional, freely willed actions by the uncovering of their meaning. Habermas, indeed, suggests that the understandability of seemingly causal connections points towards the possibility of emancipation from their false power.

Habermas' theory relies on a cognitive account of psychoanalysis. It hinges on the questionable efficacy of insight in bringing about the emancipation from symptoms. Similarly, Habermas' strict insistence on a division between the methods for the natural and the human sciences is open to criticism: it implies a division of the world into a natural world subjected to causal necessity and human sphere where causal constraints on free will and agency can only be temporary (Keat, 1981). It would go beyond the limitations of this paper to give a discussion of determinacy and free will; suffice it to say that without the causal efficacy of human motives or decisions on their implied acts, free will could never express itself (Bhaskar, 1979).

Another author who examines the link between explaining and understanding in the human sciences is Bhaskar (1979). His realist theory of science rejects the Humean regularity model of causality. Regularities, according to Bhaskar, can only be observed in controlled experiments in closed systems. In particular, falsification as a criterion for the rejection of hypotheses cannot be used in open systems, since the constellation of frame-conditions only allows for the expression of causal mechanisms on special occasions. This observation leads Bhaskar to base his theory of science on the assumption that causal generative mechanisms are really existing in the world around us. Since falsification cannot be a criterion for rejecting their existence, they cannot necessarily be used for predicting events.

Bhaskar's theory of knowledge (Bhaskar, 1975) has been applied to psychoanalysis and psychiatry by Will (1980, 1983, 1984). Will's conclusion for the methodology of these disciplines is that the search for explanations with the help of generative mechanisms makes hermeneutic approaches unnecessary and undesirable. Bhaskar himself seems to suggest otherwise (Bhaskar, 1979). He argues that the natural sciences arrive at the knowledge of generative mechanisms through their direct observation or the observation of their effects, as in the case of electrical or gravitational fields. The human sciences need a hermeneutic approach for the *definition* of their generative mechanisms. The differentiation of, for instance, causally effective reasons from mere rationalisations, or lies, is possible by comparing the stated reason with its context; that is, the situational and personal circumstances. Naturally, the statement of a reason by itself might change our appreciation of somebody's personality – we encounter here, again, the hermeneutic circle. Bhaskar thus accepts understanding as a legitimate method for arriving at generative mechanisms in the human sciences. He fails to discuss, however, the logical relationship between hermeneutics and the testing of hypotheses.

A logical framework of the interaction between understanding and explaining

The strength of causal analysis is most obvious where predictions can be made, or where technical control of the environment can be achieved. The logical structure of explanations has been examined by Hempel & Oppenheim (1948); both Nagel (1959) and Popper (1969) have described criteria of adequacy for explanations in general, and for psychoanalysis in particular. Stockman (1983) has delineated the controversies between realist and Popperian approaches to causal explanations, and has suggested that these are at present not decidable (Stockman, 1985).

According to Jaspers (1963), understanding derives its validity from two sources. On the data side, *objectively observable behaviour* or artifacts like letters, drawings and the like can be analysed by several examiners. Their understanding of the data within their context can be compared. Jaspers calls the understanding of objective data interpretation, a choice of terminology which is compatible with everyday language.

Understanding, as long as it is based on objectively observable data, requires, in addition, the experience of plausibility in the observer. This experience of plausibility, or *evidency* in Jaspers' terminology, does not depend on concurrent empirical validation. It is plausible, for example, that someone who has been disappointed in relationships might consequently be suspicious about the motives of others. Where does this experience of plausibility or evidency come from? A necessary condition for the possibility of understanding is that human beings can empathise with each other. There are several levels on which this can be illustrated. As social beings humans use an array of inborn gestures and expressive utterances. For example, the ability to laugh and cry is retained in congenitally deaf and blind people, and these expressions are understandable independently from cultural background and personal experience. A shared physical and social environment facilitates understanding, but even foreign cultures can be understood by learning the rules of their language and their social institutions (Malinowski, 1922). Since the rules linking code signs to coded message are arbitrary (Saussure, 1974), the breaking of a code consists of an attempt to unravel internally the meanings of signs, relating them reciprocally to the whole message. Wherever human cultures have created systems of signs or symbols, the hermeneutic method will, therefore, be the appropriate method of analysis.

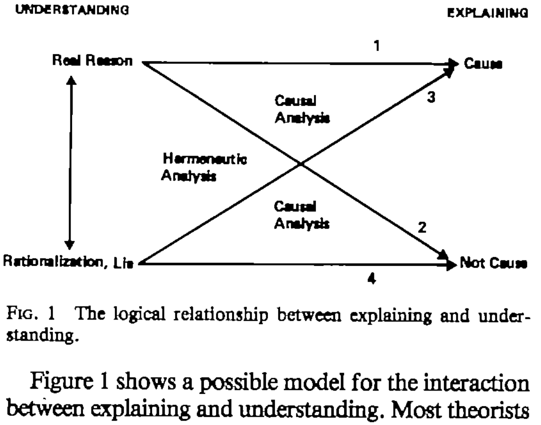

FIG. 1 The logical relationship between explaining and understanding.

Figure 1 shows a possible model for the interaction between explaining and understanding. Most theorists agree that causal explanations, before they become established, have to go through a stage of being tested as hypotheses. How hypotheses are arrived at in the first place often remains obscure. A common approach in psychopathology is to start with understandable connections, to make their components operational, and to test them in order to arrive at a correlation and, hopefully, a causal connection. It is understandable, for example, that a single mother without support and with many children to look after might easily slip into a depressive state after a serious loss, particularly if she has been sensitised to loss by a previous important bereavement, or if her mother, the traditional source of help, is not available (Young & Willmott, 1962; Brown & Harris, 1978). This understandable connection can be transformed into a hypothesis to be tested by empirical means (Fig. 1, arrow 1). It is essential to differentiate between the claim for truth of the understandable connection and that of the causal hypothesis. The former depends mainly on the psychological plausibility of depression developing from loss under certain circumstances. The latter hinges on the statistical persuasiveness of empirical results.

It is conceivable, in contrast, that an understandable connection, for instance between the loss of an organ and depression, is not borne out in causal analysis (Fig. 1, arrow 2). Although a causal relationship is not confirmed by the empirical data, a particular case can still be legitimately understood, if the connection is psychologically plausible. Although hysterectomy might not lead to an increased incidence of depression (Gath & Day, 1982), a case of depression after hysterectomy can still be understood on the basis of this connection.

Researchers are less likely to derive hypotheses from plainly disingenuous reasons (Fig. 1, arrows 3 and 4). A case could easily be construed, however, of a patient with occult carcinoma of the pancreas who claimed that he was depressed *because* he was terminally ill. Empirical testing of this psychologically clearly absurd hypothesis (which might have been classified as a nihilistic delusion by the clinical observer) could, however, lead to a medical and statistical confirmation (Fras *et al*, 1967; Fig. 1, arrow 3). Similar examples could theoretically be adduced for implausible rationalisations which prove to be empirically false if adopted as hypotheses (Fig. 1, arrow 4).

If the decision whether some factor is causally relevant or not lies with the empirical testing of hypotheses and is logically independent from the psychological plausibility of the postulated connection, it could be argued that the understanding of meaningful connections has nothing to contribute as a method of enquiry to the final outcome of scientific investigation (Will, 1983). At best it provides a heuristic tool for the formation of hypotheses. As long as no technological paradigms are being exploited, like imaging techniques or hormone assays, scientific investigation in psychiatry will naturally fall back on understandable connections for the production of causal hypotheses. In addition, the hermeneutic method has remained a part of diagnostic instruments in clinical research, like the PSE (Wing *et al*, 1984), which continually requires the examiner to decide whether symptoms or distress exceed the degree understandable from the patient's actual experiences and background. Here, and even more in clinical psychiatric practice, a wholly objective, operational system of diagnosis and assessment, although conceivable, has not yet been achieved.

Understandable connections can immunise the corresponding causal hypotheses against rejections (Kuhn, 1962). It is plausible, for instance, that middle-class psychiatrists find it easier to empathise with patients of their own class and, therefore, are less likely to classify their beliefs as delusional and to make a diagnosis of schizophrenia than with working-class patients. With seemingly supportive empirical results (Hollingshead & Redlich, 1958), a labelling theory of schizophrenia was quickly established. It needed much clinical awareness and research stamina to reject this theory (Goldberg & Morrison, 1963). Even the pseudo-plausibility of psychoanalytic 'as if' understanding was able to sustain, for example, the idea of schizophrenogenic mothers (Fromm-Reichmann, 1948) against mounting empirical evidence, an idea which was only disbanded after a considerable research effort (Leff, 1985).

Because of the central role understanding plays in psychiatry, it has to be recognised when it occurs. Its inner logic and limitations have to be appreciated, so that no unjustified claims are made (Storr, 1983). There is a moral obligation to use and improve understanding both in medicine and in human relations in general. The failure to do so is amply and painfully documented in the abuse of medicine and psychiatry under authoritarian regimes. Since both instrumental intelligence and empathy have survival value for a species, it can only be hoped that man's ability to find working explanations which lead to advanced technology is matched and tempered by his ability to empathise with others' way of thinking and feeling. In order to avoid pseudo-scientific claims, however, the fusion of biological and hermeneutic concepts, to use Gellner's terms, should be recognised and rejected.

The Evaluation of a Hostel Ward

A Controlled Study using Modified Cost–Benefit Analysis

C. HYDE, K. BRIDGES, D. GOLDBERG, K. LOWSON,
C. STERLING and B. FARAGHER

A controlled modified cost–benefit evaluation of a hostel ward caring for new long-stay patients is described and results are presented for the first two years. In some respects the residents of the hostel ward had fewer psychotic impairments than those remaining on the wards of the district general hospital, mainly because the latter seem to continue to acquire such defects, while the former have remained relatively unchanged. The hostel ward residents also develop superior domestic skills, use more facilities in the community, and are more likely to be engaged in constructive activities than controls. These advantages were not purchased at a price, since the cost of providing this form of care for these patients has cost less than care provided by the district general hospital.

In spite of the current policy of shifting the emphasis of psychiatric care from hospital to the community, mental hospitals and psychiatric units of district general hospitals (DGHs) have continued to accumulate a number of long-stay patients who require continuous nursing care (Mann & Cree, 1976; Bewley *et al*, 1981; McCreadie *et al*, 1983; Levene *et al*, 1985). Even when long-stay patients have been discharged, there is evidence to suggest that few achieve full independence from hospital services (Howat & Kontny, 1982). Further, studies on community facilities such as hostels, small hotels and group homes have reported on the selection policies they may operate, which exclude the more severely disabled or disturbed patients (Hewett *et al*, 1975; Hewett, 1979; Ryan, 1979; Ryan & Wing, 1979).

Remaining in hospital for long periods may give rise to both clinical and social disadvantages for patients with chronic psychotic illness. The social milieu, particularly on an acute admission ward, may become too emotionally arousing and cause them to relapse into florid symptoms. The needs of these patients may be taken for granted by the staff when their attention is distracted by the demands of floridly disturbed and newly admitted patients. Further, it may progressively disable a person for life in the outside community when the social milieu and management practices of a ward prevent patients from being responsible for domestic tasks such as cleaning, cooking, and laundry, as well as outside activities such as shopping and gardening.

In view of these disadvantages, other forms of care for long-stay patients have been considered which may be more appropriate for meeting both their care and accommodation needs, and for helping them to become more equipped to cope with the demands of life outside in the community. Wykes (1982) and Wykes & Wing (1982) reported preliminary evidence which indicated that the care of these patients – excluding the elderly and those with organic brain syndromes – may be better in a hostel ward rather than in hospital; this study also compared revenue costs of a hostel ward with care in a mental hospital.

The purpose of this paper is to present details of a controlled modified cost–benefit evaluation (Glass & Goldberg, 1977; Goldberg & Jones, 1980), in which the care of long-stay patients in a hostel ward – called Douglas House – is compared with the care provided by the psychiatric unit of the DGH.

The Department of Psychiatry at the University Hospital of South Manchester was first opened in 1970. It is a psychiatric unit in a teaching DGH and has a full catchment area responsibility for approximately 230 000 people. The unit does not have access to any long-stay beds in a large mental hospital. Despite an active rehabilitation programme, use of local authority hostels and care by community psychiatric nurses, since 1970 we have accumulated a number of patients under the age of 65 years who have needed to remain in hospital for longer than six months. They are our most disabled patients in that they have resisted all attempts to resettle them in the community: their common characteristic is that they need intensive nursing care.

Douglas House is a ward of Withington Hospital, and its residents are legally in-patients who are in receipt of 24-h nursing care, albeit in a Victorian house just over a mile from the main hospital. It has been described in detail by Goldberg *et al* (1985). During the period of the evaluation, the number of patients living there has never been more than ten. We first carried out an overall comparison of non-financial effects ('soft' costs and benefits), and then considered what each service costs ('hard' costs).

Hypotheses

At the beginning of the evaluation, the following hypotheses were formulated about the non-financial effects of being cared for in Douglas House compared with the care being provided by the DGH unit (Goldberg, 1983):

(a) that there would be a reduction in problem behaviours and impairments displayed in the residents;
(b) that residents would have fewer episodes of acute psychosis than hospital patients;
(c) that residents would have significantly more socially adaptive behaviours;
(d) that residents would spend significantly more time than patients in the DGH doing socially useful activities;
(e) that residents would be more satisfied with their living conditions, and would not wish to return to the hospital.

Method

Patients

Before the start of the study, all patients in the Psychiatric Unit of Withington Hospital who had been in hospital for at least six months, were in the age range 16–65 years, were in need of 24-h nursing care, and were not thought to constitute a serious hazard to public safety were identified. Only 20 patients satisfied these criteria; of these, 18 patients were eligible and consented to be in the study while a further 2 refused to co-operate. Subjects were approximately matched in pairs in terms of their potential for rehabilitation based on duration of illness, hospital diagnosis, extent of psychological impairments and extent of remediable problem behaviours as measured at our baseline assessments.

It required considerable ingenuity to produce two groups of nine patients each of whom matched a corresponding subject in all these respects. Although no attempt was made to match the patients for age, sex, or research diagnosis, the two groups turned out to be matched in these respects as well. The index group to be transferred to Douglas House was chosen by the toss of a coin.

When places subsequently became available at Douglas House, further eligible patients were identified and introduced into the study in pairs. As we aimed to ensure that the two groups remained broadly comparable with one another, we examined the effects of the overall matching of the new pair being offered first one way round, then the other. It turned out that the overall matching was always preserved, so the allocation of each member of a pair was randomised. We are reporting results for the first 22 patients (11 pairs) to complete two years in the study.

The two groups

In the index group, the management of each resident is individually formulated and structured by a rehabilitation programme which aims to help the resident to improve and maintain his or her self-care, domestic, and community skills as well as to change specific problem behaviours. Nursing is organised on behavioural lines under supervision of the clinical psychologist, with a reward system of points which are exchanged for money on a weekly basis. Patients are encouraged to follow their own leisure and social pursuits and they invariably take part in group activities that they arrange for themselves with the staff, such as going to the cinema, theatre, pubs, or restaurants. Patients who had to be returned to the hospital are still considered to be within the index group, both for non-monetary and monetary effects of the analysis.

In the control group, patients have access to comprehensive facilities of the Occupational Therapy, Industrial Therapy, and social and recreational departments of the hospital and they are able to use community amenities as they wish. Patients who were discharged into the community are still considered within the control group.

Measures

Non-financial effects ('soft' costs and benefits)

Problem behaviours and impairments were measured by the Psychological Impairment Rating Scale (PIRS) (Jablensky *et al*, 1980) and the Remedial Problem Behaviours scale developed at the Maudsley hostel ward (Wykes, 1982). We were informed that ten factor scores can be computed from the PIRS which account for over 90% of the variance (Jablensky, personal communication). Of these, we predicted that our treatment programmes might have beneficial effects on four: psychomotor inhibition, non-assertiveness, parathymia, and indifference. We also examined the 'overall impression score' and the total item score.

The clinical state of the patients was measured by the Present State Examination – PSE (Wing *et al*, 1974), the Mini-Mental State – MMS (Folstein *et al*, 1975) and the Krawiecka scales (Krawiecka *et al*, 1977).

Socially adaptive behaviours and socially useful behaviours were measured by use of a social facilities checklist (Wykes, 1982) and a television substudy. Each patient was interviewed by a social worker in a television studio for 15 min on a topic concerned with how the patient spent his or her leisure time. During this they were offered coffee and biscuits and the studio was so arranged that the patient had to pour out the coffee and pass this and biscuits to the interviewer. By using a split-screen technique, details of social and eating behaviours were recorded. These were later rated by raters who were blind to which group the patients were in and again by two speech therapists who made ratings on clarity of speech and communication skills.

Use of time was assessed with a time budget. This consisted of standardised observations of what the patients in each group were doing with their time between 0800 h and 1030 h on three consecutive weekdays and a weekend. Trained observers who worked in shifts tracked down each subject every 30 min and as discreetly as possible noted what the patient was doing in terms of a predetermined set of behavioural categories. Reliability in their observations was established so that the lowest percentage agreement between the observers was 81%.

Satisfaction with living conditions was assessed with patient's attitude scales (Wykes, 1982). These scales deal with a patient's satisfaction with eight aspects of his (or her) care: his bedroom, meals, nursing staff, other residents or patients, the regime, his occupation, attitude to discharge, and medical information.

Procedure. Apart from the time budgets, all these assessments were carried out before patients were allocated to their experimental groups. Thereafter they were repeated every six months, with the exception of the PSE and MMS, which were repeated annually. Ratings were made in the community for those patients who were discharged from either group.

The time budgets were carried out at the end of the first and second year. The first time budget was carried out with all patients in their respective group. However, on the second occasion, the original pairing could not be maintained, since patients had been discharged from the control group, and others had returned to hospital from Douglas House. Accordingly, only those patients at Douglas House and the control group still in hospital were compared.

Financial effects

Costs have been analysed and are presented in two ways: first as average daily costs per patient across the two settings; second as the average annual costs of providing care for a patient regardless of where he was during the period of the evaluation. The first method includes only National Health Service costs, while the second includes local-authority costs as well, thus representing the true costs to society of caring for these patients.

In calculating these costs, several assumptions were made:

(a) Capital costs were included.

(b) The total revenue costs of the hostel ward did not include the costs specifically concerned with its evaluation.

(c) Patients in both index and control groups were treated as homogeneous.

(d) It was assumed that Douglas House would run at full capacity; this was thought reasonable both clinically and managerially.

Four categories of costs associated with each form of care were considered.

Capital costs. These refer to the costs of replacing and upgrading the hostel ward compared with the equivalent costs of replacing the total psychiatric unit. The latter is physically separate from the other DGH buildings, making computation of capital costs straightforward. It is assumed that the capital costs would be incurred at some time in the present, although the life of the buildings and hence the benefits from using them would be over 30 years and 50 years respectively. The capital costs were therefore converted to an annual equivalent, using a discount rate of 5%.

Revenue costs. These refer to costs of direct care provided by nursing and non-nursing staff; investigation and treatment costs; and general service costs. All medical records, prescription charts, and nursing records were examined and careful records were made of use of hospital facilities, medical problems, investigations, medication, and evidence of psychiatric relapse throughout the two years. A careful record was also kept of all visits by staff, to measure the service utilisation of each group.

Calculation of all the nursing costs of Douglas House were based on the actual occupancy and actual nursing levels over the two-year period of the evaluation, and repeated assuming full occupancy and a full establishment level. The nursing costs for the hospital were calculated from a 'professional time exercise' mounted over a two-week period and covering 24 h of each day, during which all professional staff in the DGH psychiatric unit systematically recorded, on a standardised form, details of time spent with a variety of patients. This provided information on the amount of time all professional staff were devoting to the control patients in the DGH unit, and takes account of time spent in face-to-face contact with individual patients, time spent discussing the patient on ward rounds, and administrative time. This information was then costed and based on staff salaries. The staff were of all ranks and training and there was 100% co-operation.

General service costs were derived from specialty costing information collected by the health authority. The nature of their accounting system made it possible for the health economist (KL) to have details of the general service costs that were specific to the individual wards of the psychiatric unit in the DGH as well as to Douglas House, which included costs for rates, electricity, telephone, maintenance, food, and other consumables.

Local-authority and Home Office costs. During the period of the evaluation, two patients from the control group lived in local-authority hostels and night shelters after their discharge from the DGH unit, and a third patient spent time in prison. Costs calculated for providing these services were based on figures available for 1983, as published by the Chartered Institute for Public Finance Accountants.

Other social costs. These costs include those falling on the family, as well as any offset of costs due to employment of patients, but exclude transfer payments such as Social Security benefits, which are ignored in the analysis. Although we made efforts to examine the financial burden on the families concerned, it appeared that for these particular patients this was negligible, and none of them gained employment. Such small costs as existed were similar in the two groups, so they were ignored in the present analysis.

Results

Three patients had to be returned to the main hospital from Douglas House. One of these could no longer be nursed in a domestic setting because of progressive ataxia which put him at serious risk of personal injury when climbing stairs to his bedroom and when doing things in the kitchen. Two other residents demonstrated unremitting behavioural problems when initially confronted with the demands of ordinary domestic living and graded behavioural programmes. Both showed acting-out behaviour patterns, with firesetting, exhibitionism, and aggressive outbursts, and it was noteworthy that their maladaptive behaviours quickly remitted once they were back in hospital again.

As it is important to assess the new service irrespective of whether patients were able to benefit from it, the analyses based on the complete group of 11 patients originally assigned to the index group with their 11 controls are reported. However, it is also of interest to study the effects of the new service on those whom we were able to manage there, so we have also examined data based on the 8 patients who did not have to return, together with their 8 matched controls.

There were six men and five women in each group, with an average age of 42 years (s.d. = 14.0). On average the duration of their illness since their first admission to hospital was 12 years, the accumulated time they had spent in hospital was 5 years, and the period of their current admission was 3.5 years. The commonest diagnosis in each group was schizophrenia (14 patients), while the remainder were suffering from epilepsy, organic mental states and manic–depressive illness.

PSE-based Catego classes for these patients were Schizophrenic Psychoses Class S+, index group 8, controls 4; Uncertain Psychotic/Retarded Depression O?/R, index group 2, controls 2; Manic and Mixed Affective Psychosis M+, index group 0, controls 3; Other Psychoses O+, index group 0, controls 2; Obsessional Neurosis B+, index group 1, controls 0.

Non-financial effects

Problem behaviours and impairments. The results for the PIRS scales are shown in Table I for the complete set of 22 patients, using ANOVA with repeated measures. It can be seen that the hostel ward patients are significantly less 'non-assertive', and significantly less 'indifferent' than those remaining on the wards, although other variables did not reach statistical significance. If the analysis is confined to the reduced group of 16 patients, then the 'overall impression' based on the PIRS becomes significant, as shown in Fig. 1. There is a sharp decrease in psychomotor inhibition for the index group immediately on entering the experiment, but thereafter the two groups slowly deteriorated at an approximately equal rate. Other significant differences in favour of the index group were non-assertiveness and indifference.

The 'remediable problem behaviours' scales showed no consistent changes with time nor any significant differences between the groups for 'publicly undesirable behaviours', social skills, hygiene and self-care. For domestic skills there was a significant difference ($F = 7.01$; $P < 0.02$) favouring the index group, which showed a large improvement in the

first six months but no subsequent improvement, whereas the control group showed a slow but steady improvement with time. In each group there was a significant improvement with time in community skills ($F=3.36$; $P<0.02$), but no inter-group differences.

Episodes of acute psychosis. There were no significant differences between index and control groups for any rating measured on the Krawiecka scales, including affective symptoms, and positive symptoms; nor were differences demonstrated between the groups at any time point with the PSE.

For the reduced group it appeared that the control group accumulated more negative symptoms on the Krawiecka scales, but this fell short of statistical significance.

Socially adaptive behaviour. For those remaining in Douglas House, use of social facilities increased for the index group as soon as they arrived, and was sustained thereafter. The differences between the groups was significant and was largely accounted for by an increased use of the public house, cinema, and post office ($F=2.6$; $P<0.05$). There were no significant differences in social deficits or communication skills demonstrated in the television study.

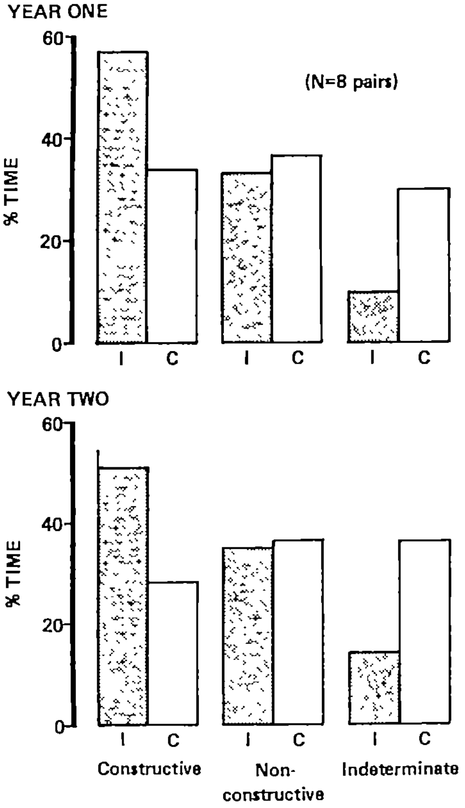

FIG. 2 Time budgets at one year and two years (I = index; C = controls).

Time spent on socially useful behaviours. As some specific behaviours had such low frequencies, they were collapsed into three categories: 'constructive' (e.g. eating, self-care, working, conversation); 'non-constructive' (e.g. doing nothing, lying in bed); and 'indeterminate' (e.g. on leave, whereabouts unknown). In both years when time budgets were carried out, the Douglas House patients were spending significantly more time doing socially constructive activities than the controls. Both groups were similar in terms of the proportion of their time spent doing non-constructive activities (Fig. 2). We thought it unlikely that those unavailable for observation and thus classified as 'indeterminate' were in fact engaged in constructive activities.

Satisfaction. We did not think it meaningful to make direct comparisons of satisfaction between the two groups, since several members of the control group were either in the community or in other forms of institutional care; we therefore confined our attention to the index group. The two residents who were transferred back to the DGH were clearly dissatisfied with Douglas House and the demands of the rehabilitation programme. However, repeated measures of satisfaction assessed by the attitude scale consistently showed that the remaining residents were satisfied with life there. At two years, all said they liked the food, liked the other residents and considered that they had enough to do. The majority (7/8) said they had enough privacy, liked their room, could talk to the staff and found them friendly, felt that they had enough freedom and that any complaints would be dealt with, had been given enough information about their illness, liked the work around the house, felt they had enough to do during the evenings, and did not want to change anything. Five residents had thought of leaving, four said they had plans to do so, and only three wanted to stay indefinitely. When asked to compare life at Douglas House with life in hospital, only one slightly preferred hospital, one had no preference, and the rest preferred Douglas House.

Financial effects

It should be noted that certain aspects of care which provide advantages that cannot be expressed in financial terms – such as the advantages of not needing to be in hospital – also make an important contribution to the 'hard' costs of providing the service. They are therefore presented here rather than in the section on non-financial effects.

Average costs per patient-day for the National Health Service. The costs for providing each service are summarised in Table II. The capital costs for Douglas House were less than those for the psychiatric unit of the DGH, but these costs formed only a small proportion of total costs – 10% and 15% respectively. Nursing costs represented 31% of the hospital costs, but rose to 60% of the costs at Douglas House, due to the smaller number of patients being nursed and the intensity of the nursing. The costs of non-nursing care, and investigations and treatment costs were low both for Douglas House and the DGH; these costs also represented a small proportion of total costs – 9% and 12% respectively. The largest difference between the two groups was accounted for by the costs for general

TABLE II
Summary of relative costs to the National Health Service: Average costs, £/patient-day

	Index group Douglas House	*Control group DGH wards*
Capital costs: £/patient-day		
Actual occupancy	2.96	6.59
(Full occupancy)	(2.67)	
Revenue costs: £/patient-day		
Direct care costs – nursing:		
Actual staffing		
Actual occupancy	17.58	13.12
(Full occupancy)	(15.51)	
Full establishment		
(Actual occupancy)	(22.05)	(14.76)
(Full occupancy)	(19.46)	
Direct care costs – non-nursing:		
Medical costs	0.58	2.80
Non-medical costs	1.06	0.72
Treatment and investigation costs:		
Investigations	0.04	0.08
Drugs	0.83	0.91
General services (hotel costs):		
Actual occupancy	6.33	18.67
(Full occupancy)	(5.59)	
Total NHS costs: £/patient-day	29.38	42.89
Range	26.23–33.92	42.89–44.53

services, such as heating, lighting, laundry, cleaning, administration, maintenance etc. For the DGH unit, these represented 44% of the total costs, as opposed to only 22% for Douglas House. This reflects the fact that patients at Douglas House perform many of these tasks themselves.

Average annual costs of providing care for the two groups. It can be seen from Table III that residents at Douglas House continued to need the services of the hospital. Some needed short admissions during episodes of florid psychosis associated with disturbed behaviour that could not be managed at Douglas House. One needed surgical care for a fractured hip and another required close medical supervision for a suspected heart attack. The control group spend far more time outside hospital than the index group, but of this time out of hospital, 48% was spent in other institutional settings – local-authority hostel, night shelter, or prison. None of the index group were discharged to another institution. Once more, time spent in night shelters and prison must be regarded as having non-financial disadvantages as well as the effects shown in the table.

TABLE III
Comparison of service utilisation by the two groups

	Index group (n=11)	*Control group (n=11)*
Day hospital: attendances	0	573
Industrial therapy: attendances	217	383
Occupational therapy: hours	22	418

Medical time: hours/week each group		
face-to-face contact	1.0	6.7
indirect contact	3.5	12.7
Number of nights:		
in Douglas House	5743	—[1]
on wards of DGH	1286	5299
on leave	479	270
in local authority hostel or night shelter	0	783
in prison	0	90
at home, with relatives or in lodgings	533	1599
(Total number of nights)	(7829)	(7829)

1. Not applicable.

The medical staff spent less time in direct or indirect contact with patients in the index group than with the controls. Despite this, the index group were more satisfied than when they were on the ward of the hospital with information given to them about their illness and about their medication as assessed by the attitudes scale.

Some residents from Douglas House had to return to hospital; patients in both groups required medical and surgical care or psychiatric day-care; and certain discharged patients from the control group required local-authority or Home Office care. The costs of providing care to the two groups regardless of where the patients were during the two years of the evaluation showed that care in Douglas House was slightly less expensive: £10 284/patient-year, against £11 504/patient-year for the controls. However, the difference becomes substantial if the analysis is confined to the reduced group of eight pairs of patients: the cost of care in Douglas House now falls to £9240/patient-year, while costs for the controls actually rise to

£12 449/patient-year. This is because the cost of providing care for those returned to the DGH unit is added to the cost of Douglas House for the complete group of 22 patients: for this reason it is of interest to examine the costs for both the full and the reduced group.

Discussion

There are two important reasons why the results of this study should be treated with some caution.

First, the research team had to fulfil two different roles as evaluators and service-providers. They were not blind to which service each group was receiving and it was not possible for them to be independent of the new service being evaluated. Further, it was possible that as the residents became more familiar with them, this may have influenced their behaviour during their assessment interviews. However, the psychiatrists also had clinical responsibilities for the care of some of the control group, and in the evaluation they strove to be scrupulously fair and objective. In anticipation of this problem, it was expected that the major reliance on standardised assessments would minimise any possible bias effects and it was thought that most of the economic data was less vulnerable to these influences.

Second, it is not possible to generalise from these results because of the small number of patients that have been considered at this stage and because the data so far only refer to a two-year period. However, we would observe that we have included everyone produced by a catchment area of a quarter of a million in just over ten years: thus if a larger study is to be done, it will have to involve more than one district health authority. If future studies use similar measuring instruments, it should be possible to pool data between studies. It is important that such further evaluations are carried out rather than firm policies being established on the evidence of a single study.

However, the preliminary results presented support the observations reported on the Maudsley hostel ward (Wykes, 1982), that patients with chronic psychiatric disabilities gain certain advantages from this form of care. With reference to the original hypotheses considered in this evaluation, the results indicate that in some respects residents of Douglas House had fewer psychotic impairments than patients remaining in hospital. This appears to be because the control group seemed to continue to acquire such defects, while the patients at Douglas House remained relatively unchanged. The results also indicate that the residents at Douglas House acquired better domestic skills, used more facilities in the community, were more likely to be engaged in constructive activities and preferred being there rather than in hospital. In several important respects both the control and index patients did equally well, but these results suggest that Douglas House has a function in preventing or at least slowing the development of psychotic impairments, and that it provides a more suitable environment for rehabilitation than an acute admission ward of a hospital.

Although Douglas House proved unsuitable for some patients, the residents who were able to manage in this setting appeared to fall into two main groups. The first comprised patients who progressively improved in psychosocial functioning and who were able to move on to less dependent or independent settings. The second group comprised patients who remain clinically impaired and socially disabled, who did not progress much after the first six months, and who still needed continuous nursing care. In this group, when a new behaviour was no longer rewarded, it tended to disappear. For them the hostel ward was either preventing or perhaps slowing down the rate of further deterioration and appeared to be providing them with a better quality of life.

The results of the economic evaluation indicate that these advantages do not have to be purchased at a price when the costs of this form of care are compared with the costs of caring for these patients in a DGH unit. Even when the entire group of patients are considered, irrespective of where they were during the period of the evaluation, the costs for the index group were less than those for the controls. It would be expected that nursing costs are going to be high when relatively small numbers of patients are being nursed together. However, these costs at Douglas House were offset by the savings made on general service costs, partly because no domestic and catering staff were employed and because the residents were expected to contribute to the housekeeping and catering tasks as part of their daily lives.

The inclusion of capital costs, albeit approximate, suggests that the capital consequences of a policy of hostel ward accommodation are cheaper than those of accommodation in hospital units. It is unlikely that many hostel wards can be built using resources released by closing wards on DGH units, since in many areas these are already providing services from very small numbers of beds, and cannot be further reduced without causing serious adverse effects on existing services. However, moving patients from an existing DGH unit to a hostel ward should make it possible to use the released resources more effectively by offering additional places to patients who would benefit from short-term hospital treatment.

Districts at present served by mental hospitals may wish to use resources produced by ward closures to fund places in hostel wards. The present results cannot be applied to this situation, since the average costs of keeping patients in chronic wards in mental hospitals are very much lower than the costs for equivalent patients in the DGH, and some long-stay patients in mental hospitals develop disabling psychotic behaviour patterns that are less often seen among those nursed in DGH units, and these patients would require much nursing time if cared for in a hostel ward.

Psychogeriatrics 1974 to 1984

Expanding Problems and Fixed Resources

ALEX B. CHRISTIE and ERIC R. M. WOOD

The impact of a 16% increase between censuses in the population aged 65 and over, on a psychogeriatric department whose bed complement remained static between 1974 and 1984, has been studied. Demand for service, as measured by new referrals, rose by 150%, while admissions fell by 14%. The increase in new referrals was uniform across the diagnostic spectrum, but the fall in admissions was not. Functional admissions fell in all age-groups except that of women of 85 and over, while organic-case admissions other than for cases of dementia virtually collapsed. Overall admissions for dementia rose to the predicted level, but the distribution of the increase was irregular and unexpected. Admissions of males and females aged 65–74 and females of 85 and over fell relatively and absolutely, while those of women aged 75–84 and men of 85 and over were little changed. Only admissions of men aged 75–84 alone increased in real terms.

Much has been written about the need to develop services for the elderly with mental illness. The *British Medical Journal* (1978) drew attention to the difficulties posed by dementia in an ageing population in the UK. Kramer (1980) presented evidence of the massive problems posed by senile dementia of the Alzheimer type (SDAT) worldwide in the last quarter of the twentieth century. Increases in prevalence of 56% in more developed countries and 123% in the Third World are predicted by the year 2000. Various planning documents (e.g. Scottish Health Service Planning Council, 1980), in drawing attention to the need to divert resources into the field of dementia, carry the implicit threat of chaos spreading throughout medical services, with widespread blocking of beds by demented elderly patients for whom no alternative provision exists.

The likely impact of functional illness among the elderly is less easy to predict. Estimates of prevalence vary widely (Hasegawa, 1985), and to complicate matters further, in many centres no distinction is made between elderly and younger patients in the management of functional illness, and consequently resource allocation to the elderly is difficult to define. Nonetheless the studies of Post (1972), Murphy (1983), and Murphy & Grundy (1984) make it clear that depression, the most common functional problem among the elderly, can be very intractable – a fact which, when linked to the increased at-risk population, leads us to predict an increased hospital workload, both in-patient and out-patient, from functional illness.

The present study looks at the period 1974 to 1984, and examines the issues by analysing the experience of one hospital whose psychogeriatric-bed complement did not increase in that time. During the period in question, levels of geriatric beds within the catchment area rose from 188 to 321 beds (+71%), while levels of places in old people's homes remained constant. By the end of 1984, the private sector had not made any impact locally upon the problems of the elderly.

Local factors

The catchment area served by Crichton Royal Hospital contains 143 000 people scattered over some 2500 square miles. Psychiatric resources are concentrated in Dumfries (population 30 000), the only large centre within the catchment area. The elderly are mainly to be found in scattered small communities up to 90 miles from the source of psychogeriatric services.

Despite distance problems, every effort was made to provide a prompt and effective service. The patients were seen initially by a consultant in one of several settings: 61% were seen at home, 25% were seen in the wards of other hospitals, 8% in old people's homes, and the remaining 6% in a variety of settings. Follow-up investigations were undertaken by medical staff, community nurses, or social workers. Emphasis was placed on dealing with the situation locally, despite problems of communication and co-ordination of service over a wide area. Early referral was encouraged, and for both medical and social reasons, admission was a policy of last resort, particularly for those living many miles from the hospital.

In both 1974 and 1984, the bed complement stood at 191 short and long-stay to deal with all psychiatric problems in those over 64. During this time, the proportion of the elderly within the population rose from under 14% to 16%.

Method

All patients admitted to the psychogeriatric wards of Crichton Royal Hospital in the calendar years 1974 and 1984 were studied with respect to age, diagnosis, and outcome at the year's end. The department's responsibility encompassed the full range of psychiatric problems in the population aged 65 and over.

We hope in due course to include details of the final outcome for this group of patients in a wider study and, therefore, emphasise only the features which reflect hospital workload in the shorter term.

In order to present a comprehensive picture of work undertaken, we looked also at new referrals from all sources – clinics, domiciliary visits, and general-hospital departments – employing the same parameters as for admissions. Patients identified as new referrals in a given year were not necessarily among those admitted in that or any other year; for example an established day-patient suffering from SDAT might be a 1982 new referral and a 1984 admission; or a patient with an acute functional psychosis might be admitted as an emergency without prior out-patient contact.

We have chosen to make only passing reference to the work of our day hospital at this time. In practice, it looks after mainly chronic cases and, therefore, serves a distinct and separate function. Furthermore, being available to only half the at-risk population, it does not reflect the work of the department.

TABLE I
Results – by diagnosis

	1974		*1984*	
Diagnosis	*Referrals*	*Admissions*	*Referrals*	*Admissions*
Endogenous depression	38	35	44	30

Late paraphrenia	2	9	16	4
Other functional	20	12	43	4
Total functional	63	66	135	46
SDAT	43	46	113	68
Multi-infarct dementia	11	28	35	17
Total dementia	54	72	148	85
Toxic confusional states	10	20	19	7
Other organic	3	2	8	2
Total organic	67	94	175	94
Grand total	130	160	310	140

Results

Table I gives details of referrals and admissions. Referrals rose by a factor of 2.5, from 130 in 1974 to 310 in 1984. The number of persons admitted fell slightly, from 162 in 1974 to 140 in 1984. Readmissions during the limited follow-up period were few and played no significant part in the overall picture.

In order to make our results more manageable but at the same time more detailed, we have combined all functional cases into a single group, and formed a second compact group from the dementia – SDAT and multi-infarct dementia (MID). In Table II, the results are separated by age and sex.

Organic cases excluded in this revised classification were few, and more importantly did not contribute to long-stay placements. As a result they had only a short-lived effect on the service overall.

Table II also includes information on the demographic changes arising within the at-risk population. The familiar pattern of greatest increase in the population aged 75 and over is repeated.

Male functional referrals doubled from 19 to 38 between 1974 and 1984; admissions halved from 23 to 12. Changes in a similar direction were even more marked among female functional cases. Whereas in 1974 referrals and admissions both stood at 43, by 1984 referrals had risen to 97 and admissions had dropped to 34.

The picture with dementia groups was quite different. Male referrals rose from 19 to 37, while admissions rose from 25 to 35. There was a proportionately greater rise in female referrals, from 35 to 81, but only a slight increase in admissions, from 49 to 51. A point of interest is that the mean scores of the 1974 and 1984 dementia groups on the Crichton Royal Behavioural Rating Scale were remarkably constant, at 27.27 (s.d. 6.57) in 1974 and 26.87 (s.d. 6.46) in 1984.

The upward trend in referrals was uniform across the various age, sex, and diagnostic groups, with the exception of males aged 85 and over with a functional diagnosis. This was a tiny at-risk group of 300 and, therefore, the absence of referrals over 12 months was unlikely to represent a significant variation in the otherwise uniform picture.

The picture with functional admissions was one of decline, again with one exception. Females of 85 and over showed a rise from 3 to 5 admissions, and while clearly this is not statistically significant, it calls for comment in our discussion.

Among demented patients, our findings were more variable. In 1984, there were rather more admissions of males aged 75–84, a slight increase in admissions of males aged 85 and over and a perceptible fall in those of males aged 65–75. Among female age subgroups, on the other hand, there were falls in admissions in two, the exception being the rise among those aged 75–84.

Demographic changes as outlined in Table II account for only a small proportion of the increased number of referrals, and their impact on admissions is also limited. They serve to reinforce the downward trend in admission of males and females aged 65–74, irrespective of diagnosis. The group of females aged 75–84 with a diagnosis of dementia recorded an increase in admissions commensurate with the percentage

TABLE II
Results (revised classification) by age and sex

	Grand total	63	135	66	46	54	148	74	85	+16%

increase in the at-risk population, while the group of males in the same age and diagnostic category recorded a true increase. By contrast, demographic change only served to emphasise the fall in functional admissions, male and female, in this age group. The increase in functional admissions for those 85 and over exceeded the demographic increase, but with such tiny numbers it would be rash to dwell on such a change.

TABLE III
Observed v. predicted age/sex distribution of 1984 admissions (prediction based on the age/sex distribution of the 1974 dementia and functional admissions adjusted for the overall increase in the over-65 population, and for the increase in population within each age/sex band in Dumfries and Galloway)

Age	*1984 dementia admissions*			
	Male		*Female*	
	Observed	*Predicted*	*Observed*	*Predicted*
65–74	9	13	9	12
75–84	18	8	33	30
85+	8	7	9	16
Total	35	28	51	58

$n = 86$
Comparing observed with predicted admission, $\chi^2 = 18.10$, d.f. $= 5$, $P < 0.01$

Age	*1984 functional admissions*			
	Male		*Female*	
	Observed	*Predicted*	*Observed*	*Predicted*
65–74	10	9	18	17
75–84	2	8	11	10
85+	0	0	5	2
Total	12	17	34	29

$n = 46$
Comparing observed with predicted admissions, and combining 75–84 with 85+ age groups for both sexes, $\chi^2 = 6.00$, d.f. $= 3$, $P \simeq 0.20$.

During the decade in question, important developments occurred in the field of community care. The work of community psychiatric nurses (CPNs) was extended to cover the whole catchment area. This has resulted in an increase in the average monthly return of CPN home visits, from 250 to 450 (+90%). Because of the inadequacy of our records, a comparable figure for medical staff 'return out-patient contacts' is not available. However, the extent to which medical-staff activity outside the wards has expanded may be gauged from the following figures. In the year April 1977 to March 1978, 187 contacts were made; in the calendar year 1984 the figure was 443. There is, therefore, substantial evidence of greatly increased extra-mural activity on the part of both nursing and medical staff while the principal changes described in this paper were unfolding.

Table III compares the actual 1984 admissions with predicted figures based on 1974 results and demographic change. In only the dementia groups are the changes statistically significant ($\chi^2 = 18.10$, d.f. 5, $P < 0.01$).

Discussion

We make no claim that the present study should be seen as representative of other hospitals' experience. Figures of the Common Services Agency of the Scottish Home and Health Department show that the admission rate for the elderly to psychiatric care in Scotland rose by approximately 50% between 1974 and 1984, while Smith *et al* (1986) report a doubling of admissions for dementia in England between 1973 and 1983. What our findings may represent is the experience of a long-established service in the aftermath of its initial development being confronted with a new set of problems in the second phase of its evolution.

After 25 years in operation, the service may be perceived by the community as rather more than the solution of last resort when they are confronted with intractable problems among the confused elderly. Such a proposition is supported by the increased referral rate, which far exceeds the increase in population and, more significantly, is not confined to the demented population. Such a view of this situation implies an expansion in the role of the psychogeriatric service without commensurate increase in resources. In practice, we did not set out to treat any given clinical problem preferentially, being content to deal on a day-to-day basis with matters of greatest urgency. A retrospective view of the situation suggests that dementia has asserted itself as the priority.

Against this background, two matters of fundamental importance call for consideration: firstly there is the fall in admissions and its causation, and secondly the probable outcome for cases who, by 1974 criteria, would have been admitted in 1984 but who did not gain access to the hospital.

Fall in admissions

Possibly the most important of our findings is that we admitted in 1984 the predicted number of patients with cases of dementia, although the sex distribution of this group was unexpected. Given that the number of available beds was unchanged, and that we have evidence from previous studies at Crichton and elsewhere (Blessed & Wilson, 1982; Christie, 1982; Christie & Train, 1984) that the dementing population is tending to survive longer in hospital, it follows that the predicted figure has been achieved at the expense of other patient groups, and to a lesser extent those dementia subgroups whose admission rates have fallen – males and females aged 65–74 and females 85 and over.

Table I illustrates the sources of loss. Among the cases with functional disorders, only hypomania has recorded an increase in the number of admissions, and here the impact is marginal. The group with endogenous depression has fallen slightly. The fall in depressive neuroses is considerable, even from a modest 1974 total. The small group with late paraphrenia has experienced a 50% reduction in admissions. The greatest drop of all has come in the 'other functional' group, largely made up of neurotic disorders flavoured with social problems, which has dropped by more than half. The conclusion to be drawn is that only the more severe illnesses have gained admission with any consistency, but not to a level commensurate with the population increase between 1974 and 1984.

On the organic side, SDAT admissions have increased selectively, while MID admissions have fallen, yielding overall the predicted number of admissions for dementia. Toxic confusional states have fallen back; the miscellaneous 'other organic' group remains small and unchanged. The explanation of the fall in the MID and toxic confusional states (TCS) groups almost certainly lies in the expanded geriatric provision locally. In his London study, Copeland (1981) showed that dementias based on vascular disease were more likely to find their way into medical as distinct from psychiatric care. Increased geriatric provision is likely to have enhanced this tendency. Cases of TCS may have gravitated towards available geriatric places in a similar fashion.

Cases not admitted

In considering the issue of cases not admitted, it is important to recognise that admission policy in 1974 may have been unduly liberal and, as a result, our projection overestimates the 1984 shortfall. We hold this to be unlikely in view of the 'catching up' in admission rates occurring elsewhere between 1974 and 1984. More significantly, we suspect, has been the reluctance of medical staff to send intellectually competent but depressed elderly people into a ward setting where constant contact with demented patients might be considered anti-therapeutic. It is also possible that the media have projected such an exaggerated view of the contemporary mental hospital as a repository for demented old people, that functional cases and their families have tolerated greater misery and distress in order to avoid such a gloomy prospect. This view is to some degree supported by the fact that the only functional group to exhibit an increase in its admission rate is that of females of 85 and over. These people are less likely than their younger fellows to have the home support to sustain them through the crisis, and may also be the most severe and intractable cases, for whom no possible alternative to admission exists.

We inevitably feel concern about the issue of functional illness among the elderly, as represented by our findings. We must either conclude that service to this group of patients has become poorer, or that the combination of family doctor, community nurse, and psychiatrist working with the patient in the community is equally or more effective in providing satisfactory treatment. It would be very comforting to believe that the latter is so, but in the absence of any positive supporting evidence we must accept the previously quoted work of Post (1972) and Murphy (1983) and suggest that a poorer service is the correct explanation.

In the dementia group, we note that the under-75 male and female admission rates have fallen, along with those of the 85-and-over females.

As in the case of functional illness, we have a choice of explanations. Of all our age-groups, the 65–74 is probably the one most likely to receive family support, and to have a spouse willing and able to contribute to management and be receptive to the concept of community care. Taken together, these factors may serve to delay or avert admission, and thereby account for our findings.

Such explanations are unlikely to apply to females of 85 and over. We know the at-risk population is rising, and that the prevalence of SDAT is at its highest in this group (Kay *et al*, 1964), and yet admissions have fallen. Recent pathological studies by Rosser *et al* (1984) point to the presence of less severe and less widely distributed lesions among the very elderly, compared with their younger counterparts. The clinical application of these findings might imply that in the older age-group, the illness is perhaps less dramatic and less frequently characterised by major behavioural problems which channel the patient towards psychiatric services. If this putative clinical analogy is valid, then our very elderly female patients may well gravitate towards the geriatric service more readily than their younger counterparts, emphasis being more readily placed on physical rather than psychiatric aspects of their caring needs.

Conclusions

We acknowledge the possibility that one-year study periods are too brief to enable final judgements to be reached. They have, however, the advantage of being manageable units of time, and for that reason allow us to attach some importance to our findings.

Our principal finding is that, contrary to expectation, functional illness gives way to dementia under the constraints of limited resources. Secondly, age has an important bearing on management of dementia. Patients in the middle band of our age-range are more likely to be admitted than their younger or older counterparts, particularly if the latter are female.

The fate of those whose admission was predicted but nonetheless failed to take place is unclear, and merits further study. We suggest that functional cases may have received a poorer standard of care, that the younger dementia group, male and female, may, at least in the relatively short term, prove manageable within the community, and that the very elderly female group, being less behaviourally disturbed and less physically fit, find their way into geriatric care or tolerant old people's homes.

The most cogent point of all is that setting up a service and allowing it to develop an acceptable style cannot be regarded as an ongoing state of grace. Unless there is continuing development, circumstances will dictate priorities, to the detriment of certain patient groups.

A Study of Firesetters in the South-West of Ireland

GERALDINE H. O'SULLIVAN and MICHAEL J. KELLEHER

A survey of 54 firesetters who had been in hospital or prison was conducted. The results confirmed earlier findings on several aspects, such as male predominance, unstable childhood and proclivity to self-injurious behaviour. Revenge emerged as the commonest motive overall and an association with alcohol was found. Only 11% of the fire-raising episodes, whether among hospital or prison groups, were truly trivial. Arsonists in prison and hospital had many features in common and generally were quite psychologically disturbed, which contrasted with those who set fires for profit. A poor outcome was found, with continuing self-harm and a high suicide rate. Our findings suggest that arson recidivism arises in at least 35% of arsonists.

The concept of fire has always attracted attention. Originally it was the gift stolen by Prometheus from the gods. Literature and our everyday language abound in references to fire. Metaphorically, it has connotations of power and passion and we are all aware of the fascination which fire holds for children. Sam Shepard (1985), writing on arson, describes setting a wooded area alight and portrays the subsequent sensuous gratification evoked by watching "the beautiful orange glow eat up the blackness" and smelling "the blue smoke cut through the mountain air".

It is not surprising that firesetting attracted the attention of early psychoanalysts. They regarded it as a regressive phenomenon related to urethral eroticism, with a sadistic element (Freud, 1932). The supposed association with childhood enuresis played a large part in the formation of this hypothesis. Objective evaluation of firesetters has arisen in more recent years, beginning with the comprehensive study of Lewis & Yarnell (1951). Some general features of fireraisers have emerged, including a male predominance, with poor social adjustment and psychosexual problems which could be related to an unstable early environment. However, despite the ubiquity and antiquity of the problem, there is a general sparsity of information, particularly in relation to the long-term outcome of these individuals.

The need for further research on firesetters is highlighted by the fact that it is now believed that in the United States at least 50% of all fires not labelled as arson are started intentionally (Blumberg, 1981).

Self-immolation by fire is reported to be uncommon. Occasionally it is used as a means of dramatisation of political protest. More often it arises in females with severe psychopathology such as a psychotic or depressive illness (Scott, 1978).

Method

Firesetting, for the purpose of this study, was defined as the deliberate setting alight of any property, including one's own clothing, which might or might not endanger life. Several methods were used to identify the sample of firesetters studied. A list of patients who were previously known to have set fire wantonly was collected by personally contacting all the senior medical and nursing staff at the two major long-stay psychiatric hospitals and four acute adult psychiatric units within the Southern Health Board of Ireland. All those approached cooperated, but needless to say some remembered more firesetters than others and the same arsonists were mentioned by several different personnel. We believe that the bias of such a sampling procedure favoured those in the middle range of dangerousness, as the trivial would have been forgotten by the respondents and the extremely dangerous would have been committed either to prison or to the Central Mental Hospital, which is the equivalent of Broadmoor.

This method yielded 37 firesetters. Seven of these were self-immolators, all of whom had carried out their self-immolation while on a hospital ward. Of the remaining 30 arsonists, eight (26.6%) carried out the firesetting act while in hospital, and for 17 (77%) of the remaining 22, admission to a psychiatric hospital was directly related to their fire-raising. As it was not possible to interview personally all of these firesetters, for a variety of reasons (no longer in contact with the psychiatric services or through death), it was decided that the case-notes should be examined in detail. Information was collected about each individual, which included his adult social environment, the circumstances of his upbringing and the recorded type of psychopathology (based on ICD-9) present at the time of the burning. A particular effort was made to clarify the circumstances of the firesetting, including any association with alcohol or drugs, whether done alone or with an

[1] Excluding 65-year-old schizophrenic

accomplice, what the likely motivation was and what were the likely consequences. If information was lacking in any of these areas, it was sought from the medical and nursing staff who had dealt with the individual.

Seventeen prisoners were examined individually for the study at Cork Jail, which serves the counties of Cork, Kerry, Waterford and Tipperary. The authors are confident that these were all the fireraisers who served time in Cork Jail during 1985, either as remand or convicted prisoners. Each admitted the burning to the examining doctor (MJK). A detailed semi-structured clinical interview was used, covering the same areas as for the hospital sample.

An effort was made to obtain a third sample comprising those who criminally burn for personal gain. These are people who set fire to their own property with a view to benefiting from the insurance or from a malicious damages claim. For the purposes of constructing such a sample, after several preliminary meetings, a two-hour discussion was arranged with three loss adjusters, who prefer to remain anonymous (a loss adjuster is a professional person employed by an insurance company to put a value on the extent of damage to property and if possible to ascertain the cause).

It was not possible to collect information from the loss adjusters on individual cases of possible non-accidental burning (because of their fears of breaching confidentiality) which could be compared in a quantitative way with the prison and hospital samples. From their point of view, non-accidental burning falls into two groups. The larger is where the property is maliciously burnt by people other than the owner. (Several of the prison population in the present study were known professionally to the loss adjusters.) The smaller group is where the property is burnt by the owners themselves.

Results

The prisoners were younger than the hospital patients and more likely to be of rural origin (Table I). The difference in mean ages between the two samples is statistically significant (t-test, $P<0.01$). One prisoner, aged 65 years, was suffering from schizophrenia and is excluded from the average age quoted for the prisoners. The difference in urban/rural origin fails to reach statistical significance.

All the prisoners were male by virtue of the sampling procedure. Within the hospital group, 86% of the self-immolators were female, but the situation was reversed for the other hospital patients, 77% being male. The prison and hospital samples did not differ in other demographic characteristics. Both showed a preponderance of single marital status (70%), lower social class (70%) and a high degree of unemployment (78%).

On examination of the childhoods of these individuals it was found that five (10%) had been reared in orphanages or some place other than the parental home. Of the 49 who were reared at home, there was mental illness or psychopathy present in the parents of 37%. Altogether an unstable early environment can be inferred for a total of 46%.

The diagnoses of psychosis and personality disorder were commonest, constituting two-thirds of the sample (Table II). For those ascribed a diagnosis of personality disorder, there was independent evidence in the history to support the diagnosis other than the act of arson itself. The paucity of those ascribed a diagnosis of depression is surprising, particularly for the self-immolators, 71% of whom were psychotic.

On examination of the tendency to engage in self-injurious behaviour, firesetters emerge as a disturbed group of individuals. A history of prior self-mutilation was present in 9 (53%) prisoners and 12 (32%) patients. Prior parasuicide had arisen in 5 (29%) prisoners and 24 (65%) patients. If cognisance is taken of the tendency to self-harm, it can be inferred that the prison sample is quite psychologically disturbed. Eight (47%) prisoners had previously been in a psychiatric hospital and four (13%) of the hospital group had previously been in prison. Overall there is considerable overlap between the hospital and prison groups. However, the prisoners were more likely to have engaged in other antisocial activities: 11 (64.7%) prisoners had a history of antisocial activities compared with 10 (27%) of the hospital group, the difference between the two groups being statistically significant ($\chi^2=3.84$; d.f. $=1$; $P<0.05$). When

No psychiatric illness	5	(29)	—		—		5	(9)

the relationship between diagnosis and symptoms was examined, those ascribed the diagnosis of personality disorder emerged as the most severely disturbed, many having engaged in prior self-harm and antisocial behaviour.

Regarding the fireraising act itself, an accomplice was present in only three cases (9%). It transpired that nine of the prisoners and ten patients had taken substantial quantities of alcohol at the time, and alcohol may have played a causative role in the act, as it appears that underlying aggressive instincts were unveiled which might otherwise have remained dormant. Only two subjects were under the influence of drugs and both of these were prisoners.

Revenge was the commonest motive in both populations (Table III). As expected, firesetting instigated by suicidal and delusional motives was more prevalent within the hospital sample, but delusional motivation was also represented in the prison sample. The motive was recorded as delusional if the fireraising arose secondary to a false belief which had developed during a psychotic illness; for example, one man set fire to cars under the delusion that the firesetting would avenge the suffering of deprived children of the world.

Where an individual attempted to influence others or enforce change to secure personal favours by the act, the motive was listed as manipulative; for example, one prisoner set fire to his cell in an effort to precipitate his transfer to another prison. The category 'motiveless' was used for those who, despite their admission of guilt, could not provide any reason for carrying out the act.

Regarding the relationship between diagnosis and motivation, revenge was the primary motive for about half of all diagnostic groups, except for the psychotic, of whom only two of the 21 cited revenge as their motive. Almost half of the latter were motivated by delusions and eight by suicidal attempts. Alcohol was present in 50% of those motivated by revenge, compared with 35% for the total, but the difference does not reach statistical significance. The targets of the revenge were diverse and included relatives, neighbours and figures of authority. Those motivated by tension-reduction tended to engage in other tension-reducing activities such as self-mutilation and parasuicide. Four of the five so motivated were recurrent firesetters.

Regarding the potential consequences of the fireraising activities, in only 11% of the cases, whether among the prison or hospital group, were they truly trivial. The prisoners' fireraising was more likely to result in serious damage to property, while only the hospital group endangered themselves or others. Generally, the prisoners were more likely to externalise their aggression, while the patients tended to direct it inwardly. This difference was statistically significant ($\chi^2 = 5.02$; d.f. = 1; $P < 0.025$).

The average time interval between the firesetting episodes and the study was 5.65 years for the hospital group. At the time of the study, of the 30 hospital arsonists, 15 (50%)

TABLE III
Motivation

Motives	*Prisoners* (n = 17)		*Hospital group*				*Total* (n = 54)	
			Self-immolators (n = 7)		*Other hospital patients* (n = 30)

were living in the community, 12 (40%) were in long term care; 1 (3%) was in prison; 1 (3%) had died of natural causes and 2 (7%) had died by suicide. This latter finding contrasts with a suicide rate of 13/100 000 (0.013%) described by Clarke-Finnegan & Fahy (1983) in a population-based study in the West of Ireland. Overall, a poor prognosis with a high suicide rate is the picture which emerges for hospital arsonists.

At the time of the study, from the entire sample, 19 (35%) had been involved in one or more episodes of further firesetting. Of these, seven had a recurrence within the first six months of the original act, and six were recurrent firesetters (i.e. engaged in repeated episodes). The remaining six had a recurrence after periods of between six months and ten years, indicating that arson recidivism can arise even after a lapse of many years.

Of the six recurrent firesetters, all were male, of lower social class, and effectively single, and had unstable childhoods. All had a psychiatric diagnosis: four were personality disordered, one was mentally handicapped and one schizophrenic. All had shown some form of behaviour disturbance: four had engaged in self-mutilation, three had attempted suicide and five had committed antisocial acts. One of them eventually committed suicide.

Material gain did not feature as a motive in this study, but it merits consideration, as the loss adjusters estimate that in Ireland, of the claims against insurance companies for property loss due to fire, there is suspicion that the fire is engineered by the owner in 5% of the cases and there is convincing evidence in about 1%. Typically, those motivated by material gain burn their own property, which is usually overinsured in a pre-planned calculated way, often employing accelerators (e.g. petrol). They are of average or above-average intelligence and mentally normal, and generally come from stable families with assets. Their personalities are resourceful, they have the ability to generate property, and they subsequently deny committing the act. This contrasts with hospital and prison arsonists, whose firesetting arises impulsively against a background of mental instability, personality problems, limited intelligence and deprived childhoods.

Discussion

Literature of the nineteenth century indicated that arson was usually a crime committed by females. Currently it is generally accepted that males predominate and comprise approximately 85% of all arsonists (Lewis & Yarnell, 1951). However, others have suggested that the supposed rarity of female arsonists could be apparent rather than real, due to the tendency to avoid prosecuting them for the crime (Tennent *et al*, 1971). Our results show a preponderance of males among the arsonists. However, among those who used fire for the purpose of self-immolation, there was a reversal of the male-to-female ratio. These appear to be a distinct subgroup, with severe psychopathology in the form of a psychotic illness being present in the majority.

With regard to the other demographics, our results are consistent with earlier studies along several aspects such as a large age range, low social status, high unemployment rate and a paucity of long-term psychosexual relationships. The age distribution was much less scattered for the prison sample, leading to a lower mean age, which is not unexpected, as in general the prison population is comprised of young males. In fact, our results indicate that age may be a factor which biases society's methods of dealing with firesetters. Considering the sparsity of psychosexual relationships, it is likely that the failure of these individuals to achieve or sustain relationships is part of a general inadequacy, which Inciardi (1970) has tersely described by comparing these individuals to hoboes because of the lack of emotional and social ties, together with their susceptibility to problem drinking.

Almost half the individuals in this study may have been rendered vulnerable to psychological disturbance through parental absence or parental mental illness or psychopathy during their childhoods. An unstable early environment has frequently been found among arsonists (Lewis & Yarnell, 1951; Tennent *et al*, 1971; Yesevage *et al*, 1983). Macht & Mack (1968), reporting on four adolescents, hypothesised that their firesetting represented an attempt to re-establish links with their fathers, from whom they had been separated. However, it is more likely that traumatic emotional experiences during childhood and adolescence predispose people to psychological disturbance, of which firesetting may be one manifestation.

No single diagnosis has been found to characterise firesetters. Likewise, our results showed diagnostic heterogeneity. The rather large figure of 38.8% who were psychotic is obviously a reflection of the selection procedure, as in general it is held that psychotics comprise only 10–15% of all firesetters (Blumberg, 1981). Various figures have been cited for the proportion of mentally ill firesetters who are mentally handicapped (Yesevage *et al*, 1983). Although only 7.4% of our cases were actually mentally handicapped, many more were functioning in the dull normal and low average intelligence ranges. Levin (1976) suggested that arsonists frequently have psychopathic personalities. Almost a third of the individuals in this study had personality disorder as a primary diagnosis, many more having it as a secondary diagnosis.

Despite the diagnostic variability, a consistent finding was the proclivity of individuals of all diagnostic types to engage in self-destructive behaviour. McKerracher & Dacre (1966), in a study of arsonists in a special security hospital, found symptoms of self-mutilation and attempted suicide in 13% and 23% respectively. It appears that, for some, firesetting is an activity resorted to at times of despair or tension, and in this respect it is akin to self-mutilation and parasuicide.

Simpson (1975) noted that self-mutilators often have difficulty expressing their needs and emotions and generally have poor verbalising abilities. Geller & Bertsch (1985) observed the tendency of firesetters to engage in non-lethal self-injurious behaviour, and hypothesised that firesetting might be used as a communicative vehicle by those with poor verbalising skills. Mentally handicapped individuals may also use it for this purpose, and this is substantiated by the preponderance of these individuals in the motiveless category.

Ascertainment of the underlying motivation is important as it may be valuable in prevention. Revenge has been found to be the commonest motive among arsonists of all diagnostic types. Virkkunen (1974) estimated that 50% of schizophrenics were motivated by hate, often directed against society in general, and he concluded that their motives were understandable on normal psychological terms. However, in our study the motives of the psychotic were more likely to be related to their illness rather than being rational, and this is reminiscent of the findings of Taylor (1985), that 80% of the offences of the psychotic were either directly or indirectly attributable to their illness. Our results highlight the disinhibiting effect of alcohol, particularly for those whose firesetting was motivated by revenge.

Among the recurrent firesetters, the motive of tension-reduction was commonest, and two of these had some of the features of pyromania as outlined in DSM-III. These include recurrent failure to resist impulses to set fires, mounting tension prior to setting the fire and subsequent release, lack of other motivation such as material gain, and the absence of another disorder. True pyromania fulfilling all these criteria is now considered rare, even though Lewis & Yarnell (1951) estimated that up to 40% of male arsonists were pyromaniacs.

It has been suggested that fire has sexual symbolic meaning for some arsonists and therefore firesetting may be a means of obtaining sexual gratification. However, this did not emerge as a motive in this study, even among the recurrent firesetters, for whom firesetting is supposed to be a means of obtaining sexual gratification. This suggests that previous literature has placed far too much emphasis on the importance of sexual gratification as a motive among firesetters.

In contrast to the degree of psychopathology displayed by many arsonists, those motivated by material gain are generally psychologically 'normal, and their arson represents a calculated, rational act. It follows that prevention of this type of arson can only be achieved by elimination of the financial gain involved.

The poor outcome is a reflection of the general inadequacy and the degree of psychological disturbance of these individuals. Our results suggest that self-destructive behaviour tends to continue and may eventually culminate in suicide. The suicide rate of 66 per 1000 for the hospital sample (excluding the self-immolators) is markedly elevated compared with a suicide rate of 1 per 1000 psychiatric admissions found by Farberow *et al* (1971) and a rate of 1.3-2.5 per 1000 in six psychiatric hospitals (Gale *et al*, 1980). An inability to deal with aggressive instincts can be inferred, aggression sometimes being directed inwards and at other times outwards.

Bradford (1982) has suggested a linkage between homicide, suicide, and arson. Certainly the results of this study would espouse an association between suicide and arson. Furthermore, the firesetting of three individuals contained elements of danger to the lives of others, one of which represented a serious homicidal attempt. Further studies are needed to explore this possible linkage, but our results lend support to it.

Lewis & Yarnell (1951) found recurrence of arson in 30% over a 15-year period. In another study, arson recidivism was reported to be rare: in a 20-year cohort study of 67 arsonists, only three were reconvicted for arson (Soothill & Pope, 1973). However, the low rate of arson recidivism among these individuals might be apparent rather than real, due to failure of detection of further arson by the law-enforcing authorities. Among the 35% who were recidivists in our study, the fact that recurrence was most likely within the first six months implies that adequate assessment, management, and follow-up for at least six months may be potential means of prevention of arson recidivism.

Overall, the prisoners appear to be a more dangerous group, when the consequences of their fireraising and history of prior antisocial activities are considered. However, there is considerable overlap between the two populations, many prisoners showing evidence of psychological disturbance and a third of the hospital sample having a history of antisocial activity. Society's method of dealing with these appears to be haphazard and arbitary, with irrelevant variables such as age and origin playing determinant roles in the disposal of these individuals. It is generally recognised that there is a high prevalence of psychiatric disorder among prisoners. In a recent survey of those on remand in Brixton, Prison, Taylor & Gunn (1984) found major symptoms of psychiatric illness in 9% and withdrawal symptoms in a further 8.6%. Interestingly, they found that 65% of arsonists were psychiatrically disturbed. Our study demonstrates the overlap between the mental health and the criminal justice systems and also highlights the arbitrariness of society's method of dealing with these individuals.

Overview of the results of this study leads us to make certain recommendations regarding the assessment and management of firesetters. Even though no reliable prediction can be made on the diagnosis of a mentally ill firesetter, he is likely to be of below average intelligence and to display a general inadequacy in many aspects of his life. Other areas might also be usefully explored, including the ability to communicate and express emotions, the methods of dealing with tension and frustration, and the presence of problem drinking and any unveiling of aggressive instincts under its influence. Ascertainment of the underlying motivation, even though it may be difficult and elusive, should be attempted as far as possible.

Whatever setting these individuals are assigned to, there should be adequate provision of medical care and rehabilitation. Bowden (1978) has shown that nearly two-thirds of mentally abnormal criminals who get the chance of treatment show some improvement. It is likely that many have been subjected to much deprivation, beginning in their childhoods and perhaps continuing thereafter, predisposing them to a general inadequacy in many aspects of their lives. Further education of those with poor communicative skills and low intelligence scores would be beneficial.

In view of the large number who offend as a direct or indirect consequences of their illness, it is important that adequate treatment is provided, followed by suitable rehabilitation programmes. Regular follow-up examinations for at least six months, with admission at times of stress and tension, is advisable and is also likely to be a valuable preventative measure.

In conclusion, firesetting is a highly complex behaviour: it is not simply a manifestation of a basic sociopathic inclination but for many is indicative of severe underlying psychopathology. Firesetting appears to have many different meanings and determinants for various individuals, and one hypothesis alone is unlikely to explain why some resort to it. However, it is clear that many of these individuals suffer much inner disharmony, and attempts should be made to alleviate this where possible. The importance of adequate assessment and management is borne out by the potentially serious consequences of many incendiary acts and also by the high rates of arson recidivism.

Acknowledgements

We are grateful to the three loss adjustors who gave freely of their time, to the medical and nursing staff from the various hospitals within the Irish Southern Health Board who helped in the compilation of these firesetters, and to Eleanor O'Leary.

In Vivo Assay for Neuroleptic Receptor Binding in the Striatum
Positron Tomography in Humans*

H. CAMBON, J. C. BARON, J. P. BOULENGER, C. LOC'H, E. ZARIFIAN and B. MAZIERE

Using PET, we investigated the potency in six patients of therapeutic doses of neuroleptic drugs for preventing specific binding of trace doses of intravenously administered ^{76}Br-labelled bromospiperone to corpus striatum *in vivo*. Measured receptor occupancy showed a clear-cut dose-dependent saturation curve with increasing daily oral dose of neuroleptics, indicating the validity and reliability of the method when used as an *in vivo* radioreceptor assay. Following drug withdrawal in eight patients, recovery to normal or supranormal receptor availability occurred in a matter of days. The results demonstrate an approach that may help resolve controversies about, and design better strategies for, neuroleptic treatment schedules.

Neuroleptic drugs are effective in controlling acute episodes of schizophrenia. However, the relationships between dosage and clinical response remain unclear (Davis *et al*, 1983; Curry, 1985), and the indications of maintenance therapy are a matter of debate (Hershon *et al*, 1972; Heinrichs & Carpenter, 1985; Gaebel & Pietzcker, 1985). These uncertainties may be due to insufficient information regarding the access of neuroleptics to, and rate of elimination from, target structures in brain.

The reliability of neuroleptic plasma levels has been questioned because they are not consistently correlated with antipsychotic effects, although radioreceptor assay, which takes into account the active metabolites, has occasionally provided better correlations (Creese & Snyder, 1977; Dahl, 1982; Meltzer *et al*, 1983; Rivera-Calimlim & Hershey, 1984). Neuroleptic drugs levels in brain tissue do correlate with behavioural effects in rats (Campbell *et al*, 1980), but this method is seldom applicable to humans.

Blockade of the central dopamine receptors is held to be the essential mechanism in the pharmacological action of the neuroleptics (Crow *et al*, 1976). Hence, to measure *in vivo* the actual occupation of brain dopamine receptors should provide an indirect estimate of the effective neuroleptic tissue levels, by analogy with the radioreceptor assay principle.

Positron emission tomography (PET) has recently emerged as a unique tool to investigate the striatal dopamine receptors in humans *in vivo* using radiolabelled high-affinity neuroleptics (Wagner *et al*, 1983; Baron *et al*, 1983; Leenders *et al*, 1984; Wong *et al*, 1984; Arnett *et al*, 1985; Maziere *et al*, 1985; Farde *et al*, 1985, 1986). Bromospiperone is a particularly suitable radioligand for this purpose, as shown by extensive validation studies in animals and humans (Kulmala *et al*, 1981; Crawley *et al*, 1983; Maziere *et al*, 1984, 1985; Baron *et al*, 1986). This approach should provide a semi-quantitative estimate of the neuroleptic binding sites available for interaction *in vivo* with the administered radioligand, and be ideally suited to evaluate the receptor occupancy rate both during and following oral treatment with neuroleptics.

Method

Patients

Ten patients (three women, seven men) were studied (Table I) after informed consent. Their age range was 21–82 years (mean 51.2). All had been on chronic medication with oral neuroleptics for more than 2 months. The clinical indications for neuroleptic treatment (Table I) were deliberately heterogeneous in order to ensure an as-wide-as-possible neuroleptic dosage range. Some patients were also receiving benzodiazepines, anticholinergic drugs or antidepressants at the time of the study, but none was on lithium. Four patients were studied twice, first on treatment, and then after withdrawal. In all, there were six studies of patients on treatment, and eight of patients off neuroleptics for periods of 1–12 days.

In order to allow comparison between the different studies, each neuroleptic medication was expressed as a weight-adjusted equivalent daily dose of chlorpromazine (CPZ). The calculation was based on established dose equivalence (Peroutka & Snyder, 1980). When this was

1. $(S/C)_{th}$ is the age-adjusted striatum/cerebellum theoretical ratio.
2. Neuroleptic daily dose expressed as chlorpromazine (CPZ) equivalent.
3. $(S/C)_m$ is the S/C ratio actually measured.
4. P is the percentage of unoccupied binding sites calculated from equation (4).

unavailable for a given neuroleptic, we calculated it from its inhibition constant (K_I) for ^{3}H-haloperidol binding *in vitro* (Leysen, 1984), since a very good correlation between the average clinical daily dose and the K_I for ^{3}H-haloperidol binding has been established (Creese *et al*, 1976; Seeman *et al*, 1976).

PET studies

The method used has been described elsewhere (Maziere *et al*, 1984, 1985; Baron *et al*, 1986). About 1.3 mCi of bromospiperone (BSP) labelled with ^{76}Br ($T_{1/2} = 16.2$ h) was injected i.v. as a bolus with a specific activity of 330±100 mCi/µmol. The amount of bromospiperone injected was 2.75±1.26 µg. From a whole-body kinetic biodistribution study performed in a baboon, it was shown that about 25% of the injected dose was concentrated in the liver. For a ^{76}Br–BSP study in man, the radiation dose absorbed by the liver has been estimated as 1.9 rad, which is lower than that of standard nuclear medicine procedures such as bone marrow or liver scans (Robertson, 1982; Maziere *et al*, 1985). Permission to carry out ^{76}Br–BSP studies was granted by the ethical committee of the Atomic Energy Commission.

PET studies were performed on the time-of-flight positron camera at the Laboratoire d'Electronique et de Technologie de l'Informatique, Grenoble. Spatial resolution in the plane of section is about 12 mm, slice thickness about 13 mm and undetected space between slices about 3 mm using the medium-resolution mode. Seven slices were acquired simultaneously, levels being chosen from a standard PET atlas (Inoue *et al*, 1985) so that the cerebellum was studied at the lower cut and the striatum at the third cut; 1 cm and 4 cm, respectively, above and parallel to the orbitomeatal plane. A ^{68}Ge–^{68}Ga transmission scan was performed for accurate attenuation correction. A 30-min scan was acquired, starting 4.5 h after injection.

From these images, the striatum and cerebellum radioactive concentrations were obtained by means of a standardised, previously validated method using regions of interest (ROIs) (Maziere *et al*, 1985; Baron *et al*, 1986). In the four patients on large doses of neuroleptics,

TABLE II

^{76}Br–BSP relative radioactive concentrations (mean ± s.d.) showing no significant differences among subgroups for any variable

76 Br–BSP concentration	*Controls*	*On neuroleptics*	*Off neuroleptics*	*P*
Cerebellum,[1] $t = 5$ min	1.36 ± 0.52 ($n = 11$)	1.23 ± 0.55 ($n = 6$)	1.19 ± 0.21 ($n = 8$)	NS
Cerebellum,[1] $t = 4.5$ h	1.41 ± 0.41 ($n = 17$)	1.42 ± 0.27 ($n = 6$)	1.42 ± 0.20 ($n = 8$)	NS
Blood,[2] $t = 5.0$ h	0.47 ± 0.19 ($n = 17$)	0.50 ± 0.19 ($n = 6$)	0.50 ± 0.12 ($n = 8$)	NS

1. As percentage injected dose per litre of brain.
2. As percentage injected dose per kilogram of blood.

the striata could not be clearly depicted on the 4.5 h PET images because of receptor occupancy by neuroleptic treatment as shown and discussed below. Since these patients were also studied after drug withdrawal, the ROIs defined on the latter PET images were copied automatically on to the former by means of dedicated software. This was possible because of special care taken for reproducible positioning in these repeated PET studies by use of crossed laser beams projected on standardised bony landmarks.

Determination of the percentage of unoccupied binding sites

Since the cerebellum is virtually devoid of specific binding for neuroleptics (Luabeya *et al*, 1984; Martres *et al*, 1985), the difference between the ^{76}Br–BSP concentrations in the striatum and in the cerebellum represents the specifically bound ligand in the striatum (Kuhar *et al*, 1978). The fraction f of dopamine sites occupied by the neuroleptic medication can therefore be described by the following equation:

$$f = [(S_{\text{th}} - C) - (S_{\text{m}} - C)] / [S_{\text{th}} - C] \qquad (1)$$

where C is the radioactive concentration in the cerebellum, S_{th} the theoretical (expected) radioactive concentration in the striatum and S_{m} that actually measured in the study of the patient. By dividing each term by C, equation (1) becomes

$$f = [(S/C)_{\text{th}} - (S/C)_{\text{m}}] / [(S/C)_{\text{th}} - 1] \qquad (2)$$

where $(S/C)_{\text{th}} - (S/C)_{\text{m}}$ are the expected and the measured striatum-to-cerebellum radioactive concentration ratios, respectively.

The use of equations (1) and (2) relies on the assumption that the parameter C, which is measured at 4.5 h and represents both free ligand and non-specific binding, is unaffected by neuroleptic treatment.

The percentage of neuroleptic sites left unoccupied by the neuroleptic medication can be expressed as

$$\text{percentage of unoccupied sites} = 100\,(1 - f) \qquad (3)$$

which can be rewritten as

$$\text{percentage of unoccupied sites} = 100\,\{[(S/C)_{\text{m}} - 1] / [(S/C)_{\text{th}} - 1]\} \qquad (4)$$

Data analysis

From the radioactive concentration values measured in the striatum and the cerebellum, the $(S/C)_{\text{m}}$ ratio was calculated for each subject.

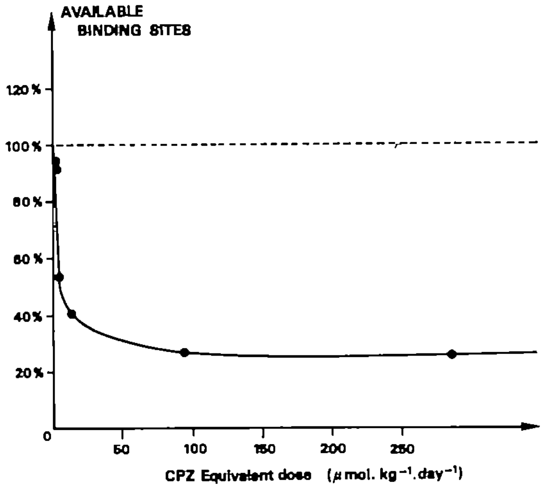

FIG. 1 Available binding sites (percentage of unoccupied neuroleptic sites) in the six ^{76}Br–BSP PET studies performed during neuroleptic treatment, plotted against the weight-adjusted neuroleptic daily dose expressed as chlorpromazine (CPZ) equivalent (CE). The data were best fitted by the bi-exponential line $P = 98 \exp(-0.3\ \text{CE}) + 34 \exp(-0.001\ \text{CE})$.

To obtain the $(S/C)_{\text{th}}$ value, data from 17 control subjects studied by the same procedure were used. However, it was necessary to adjust for age according to the highly significant negative linear regression relating S/C and age found in controls (Baron *et al*, 1986). Finally, using $(S/C)_{\text{m}}$ and $(S/C)_{\text{th}}$, the percentage of unoccupied sites was determined according to equation (4).

Results

Blood and cerebellar values

There was no significant difference between patients and controls in early cerebellar tracer uptake, late blood tracer concentration, or 4.5 h cerebellar uptake (parameter C, see methods) (Table II).

Studies on neuroleptic treatment

For patients on neuroleptic treatment, we found a clear-cut dose-dependent decrease in the $(S/C)_{\text{m}}$ ratio, which ranged from 1.81 at lowest dosage to 1.27 at highest dosage (Table I).

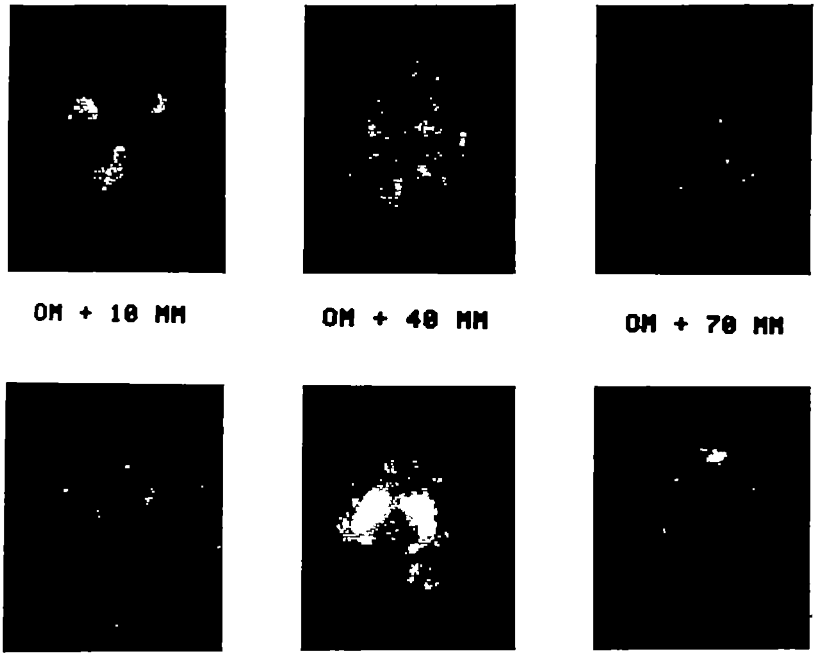

FIG. 2 ^{76}Br–BSP PET images (obtained at $t = 4.5$ h) at cerebellum level (orbitomeatal plane + 10 mm), basal ganglia level (OM + 40 mm), and corona radiata level (OM + 70 mm) in patient 6 both during high-dosage neuroleptic treatment (upper row) and one week later following 3 days of withdrawal (bottom row) (see Table I for details). These images strikingly depict the featureless pattern typically found during high-dosage treatment, indicating almost full receptor occupation by neuroleptics, and the rapid recovery of high radioactive uptake in the striatum, demonstrating in this patient a particularly fast neuroleptic washout from brain.

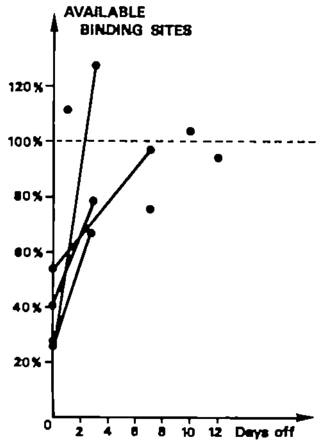

FIG. 3 Measures of available binding sites obtained in the eight studies performed after neuroleptic withdrawal, plotted against the number of days off. The lines join the values measured in four patients both during treatment and following withdrawal.

The percentage of unoccupied sites showed a striking dose-dependence (Fig. 1), and ranged from 93.7% to 26.8% for lowest and highest doses, respectively (Table I). The CPZ equivalent daily oral dose corresponding to 50% of unoccupied sites was about 6 μmol/kg (about 2 mg/kg).

Studies after neuroleptic withdrawal

Within days of withdrawal, there was a rapid trend for the $(S/C)_m$ ratio to return towards normal values (Table I). This was strikingly depicted in the four patients who were studied on both occasions, and particularly in the two patients on high neuroleptic doses, in whom the 4.5-h PET ^{76}Br–BSP image at basal ganglia level changed from a featureless pattern while on neuroleptics to the pattern of high striatal uptake typical of normal subjects 3 days only after withdrawal (Fig. 2).

When the results were expressed as the percentage of unoccupied sites (Fig. 3), it was observed that the majority of patients (6/8) fell into a somewhat curvilinear recovery line apparently crossing the 100% level by 7–12 days after withdrawal. However, the extent of recovery seemed to depend on both the withdrawal interval and the percentage of unoccupied sites during treatment; for the three repeated studies that followed this pattern, the mean percentage of recovery per day was 11.3% (range 6.2–14.9%). The last two patients (patients 3 and 6) were somewhat atypical in that both not only reached but even fell above the 100% level very early (112% and 128% one and three days after neuroleptic withdrawal, respectively), including patient 6, whose percentage of unoccupied sites during treatment was very low (27%).

Discussion

Our results are the first to show a dose-dependent occupation of human striatal binding sites by orally given neuroleptics in chronic schedule; there is no comparable data in the literature, although Meltzer *et al* (1977) found a positive linear correlation between prolactin plasma levels and oral dose of CPZ in humans up to 600 mg/day. Using ^{76}Br–BSP or other radioligands, several previous PET studies demonstrated total occupation of striatal neuroleptic binding sites by various binding sites by various neuroleptics in humans (Baron *et al*, 1983; Maziere *et al*, 1985; Farde *et al*, 1986), but none studied the full range of neuroleptic dosage and, in turn, of receptor occupancy.

The fact that despite very high doses of neuroleptics the striatum-to-cerebellum ratio did not fall to unity (Table I) may seem surprising, but it is consistent with previous results obtained in baboons loaded with unlabelled spiperone and in two human subjects administered haloperidol i.m. (10 mg) before PET study (Maziere *et al*, 1984, 1985). Errors in the estimation of occupancy rates because of competition between neuroleptics and labelled bromospiperone are unlikely, for the amount of radioligand administered was so small (5.8 ± 2.7 nmol) as theoretically to occupy less than 1% of the striatal receptors (Maziere *et al*, 1985). We believe that there was indeed full receptor occupation, but that the *S/C* ratio did not reach 1.0 because of higher non-specific uptake of bromospiperone in the striatum than in the cerebellum (Laduron *et al*, 1978; Barone *et al*, 1985), possibly a reflection of regional differences in, for example, ligand internalisation, neuronal–glial relative density, gray/white matter ratio or spirodecanone sites (Laduron, 1984; Dannies *et al*, 1984; Chugani *et al*, 1985).

Our data indicate that it should be possible to estimate the rate of striatal dopamine-receptor blockade from knowledge of the daily oral dose of neuroleptics. Although the antipsychotic effect of the neuroleptics may be more related to dopamine blockade in the mesolimbic system (Crow *et al*, 1976), there is little evidence to suggest that mesolimbic and striatal receptors respond differently to chronic neuroleptic treatment (Jenner & Marsden, 1983; Roth, 1983); unfortunately, present PET methods are not well suited to investigate this issue. From our work, however, one may infer the dose necessary to achieve full saturation of receptors, above which there may be no further therapeutic benefit, but increased risk of side-effects.

The studies performed after neuroleptic withdrawal showed return to 100% unoccupied sites within a few days (Figs 2 and 3), establishing that washout of neuroleptics from their striatal binding sites is a rapid process. Up till now, it was widely assumed that this washout was much slower, based on clinical, behavioural, and pharmacokinetic data (Hershon *et al*, 1972; Marsden *et al*, 1975; Byck, 1975; Korpi *et al*, 1984; Campbell *et al*, 1985). Our results, however, fully agree with reported neuroleptic clearance rates from plasma (Byck, 1975; Forsman & Ohman, 1977; Itoh *et al*, 1984) and brain tissue (Ohman *et al*, 1977), and with *in vivo* studies in rats (Saelens *et al*, 1980; Ferrero *et al*, 1983; Owen *et al*, 1983). Our findings may help in the design of improved treatment strategies. In addition, they strongly suggest that long-lasting remissions of psychotic patients following neuroleptic withdrawal are not due to persistent dopamine-receptor occupation. Other explanations must be sought, such as protracted neurochemical or cellular changes from neuroleptics (Benes *et al*, 1985), non-dopamine-blocking antipsychotic action of neuroleptics (Nishikawa *et al*, 1985), psychosocial therapy (Hogarty & Goldberg, 1973), or the spontaneous course of the mental illness with time (Davis *et al*, 1983).

In patients 3 and 6, the recovery rate was even faster, with levels above 100% being reached one and three days after neuroleptic withdrawal, respectively. These data presumably indicate dopamine-receptor supersensitivity (Jenner & Marsden, 1983). However, the intersubject variability in underlying mental disorder and in neuroleptic drug regimen may have affected these recovery rates, and will have to be controlled in the future.

Midsagittal Magnetic Resonance Imaging of Autism

GARY R. GAFFNEY, SAMUEL KUPERMAN, LUKE Y. TSAI, SUSAN MINCHIN and KHATAB M. HASSANEIN

Since recent reports suggest structural brain abnormalities in autistic patients, we analysed magnetic resonance imaging (MRI) scans of autistic children. Planimetric measurements were done on midsagittal MRI scans, produced with a 0.5 T superconducting magnet. Scans of 13 'high-level' autistic subjects were compared with 35 control MRI scans, read as anatomically normal by a neuroradiologist. Corpus callosal, fourth ventricular, cerebellar, cerebral, and cranial areas were measured. The fourth ventricle was found to be significantly larger in the autistic group. No other areas in the midsagittal scans differed statistically between groups. Results suggest that structures defining the fourth ventricle are anatomically altered in autistic patients.

Past investigations of brain anatomy and morphology in autistic children have yielded variable results. A pneumoencephalography study found dilated left anterior ventricular horns in autistic patients (Hauser *et al*, 1975). Computerised tomography (CT) scan studies present variable results. Several studies found significant parenchymal or ventricular abnormalities in autistic subjects (Damasio *et al*, 1980; Caparulo *et al*, 1981; Campbell *et al*, 1982; Gillberg & Svendsen, 1983); however, there were several equivocal or even negative CT studies as well (Rosenbloom *et al*, 1984; Prior *et al*, 1984; Harcherik *et al*, 1985; Creasey *et al*, 1986).

Likewise, autopsy studies offer conflicting evidence of brain abnormalities in autism (Williams *et al*, 1980; Bauman & Kemper, 1985). A Harvard group reported neuropathological gross and microscopic abnormalities of limbic structures, fourth ventricle, and cerebellum in an autistic 'brain' (Bauman & Kemper, 1985). The same group also reported abnormalities of fourth ventricle and cerebellum in autistic patients studied by CT scan (Bauman *et al*, 1985). Recently a group from UCLA reported cerebellar changes found in a number of post-mortem examinations of autistic patients (Ritvo *et al*, 1986).

Magnetic resonance imaging (MRI) offers several advantages over X-ray CT, especially in investigating the posterior fossa. There is no skull artifact in MRI as found in CT; further, MRI offers multiplanar imaging, whereas CT imaging currently is limited to transverse scans. Considering the reports indicating anatomical abnormalities in autistic brains, we felt it would be of interest to investigate the gross brain morphology of autistic children, by MRI. Thus, we wish to report our initial analysis of the midsagittal MRI scans of autistic children.

Method

Subjects

MRI scans were obtained on 13 autistic patients, seen at the University of Iowa Hospitals, who were diagnosed by the American Psychiatric Association DSM–III criteria. Age, sex, and IQ are given in Table I. IQs were mostly assessed by WISC–R (however, in one case by the Leiter and another by the Merrill–Palmer). Eleven patients were right-handed, one was left-handed, and one was mixed-handed. One patient had generalised tonic clonic seizures and was taking anticonvulsants. Two autistic patients had *café au lait* spots on physical examination, and thus had neurofibromatosis diagnosed by a paediatric neurologist. None of the patients, however, had major structural abnormalities on MRI scans.

The control group was ascertained from the records at the MRI centre. Records were examined of patients aged 4 to 19, who were referred to MRI at the same time as the autistic patients were, and whose MRI scans were read anatomically as 'normal' by the consulting neuroradiologist. Hospital records, and sometimes treating physicians, were consulted to determine significant behavioural problems or developmental delays; control patients with mention of these problems were excluded from this study. There were 35 scans of patients in childhood and adolescence that met criteria.

The control patients were referred for MRI scanning for a variety of reasons; these included a past history of histiocytosis X, headaches, Duane's syndrome, congenital optic atrophy, and others. One control child had neurofibromatosis, diagnosed by *café au lait* spots. Two control children had psychomotor seizures and were taking anticonvulsive medications. Age and sex of the controls are given in Table I. IQs and handedness of the children who served as controls were unknown; however, as mentioned, children with significant learning and developmental abnormalities were excluded from the study.

The control group used in the study is a 'medical' control group. Although it appears that this group is devoid of patients with autism, it may be argued that a 'non-medical' normal control group should be ascertained. However, for a pilot study the 'medical' control group seems adequate,

TABLE I

Demographic data of the autistic and control groups

	Autistic group	*Control group*
Number	13	35
Age range	5–22	4–19
Mean age[1] (±s.d.)	11.3±4.7*	12.0±5.2*
IQ range	60–135	—
Mean IQ (±s.d.)	84.9±26.7	—
Males	10 (77%)	21 (60%)

1. Age data in the groups were tested independently for skewness. The null hypothesis of no skewness was not rejected.
*NS (*t*-test).

especially considering the ethical issues of exposing normal children to a procedure that may require sedation. Moreover, since the medical control group was referred to the same hospital as the autistic group, referral bias would be controlled.

Procedures

The MRI scans were done on a 0.5 tesla superconducting magnet, Picker Vista MR. Scans were recorded on transparent film with a 14 cm to 4 cm scale reduction. Most of the autistic children were sedated with chloral hydrate, 50–100 mg/kg. No problems were encountered during these scanning procedures.

The midsagittal scans were projected from a photographic condenser, life size, on to a digitising tablet (Houston Instruments, Hipad) interfaced to a microcomputer (IBM PC/AT) for digitisation and area measurements. Planimetric measurements were calculated by computeraided design software (Autocad, by Autodesk). Scans were digitised three times by two investigators. The digitising was done blind to diagnostic group. Areas measured by planimetry included corpus callosum, fourth ventricle, cerebellum, cerebrum, and cranium.

Data were analysed by Pearson correlations, multivariate Hotteling's t^2, and univariate *t*-tests in appropriate applications. These statistical tests were done by the Statistical Package for the Social Sciences on a mainframe computer at the University of Iowa's Computing Center, and by SAS on mainframe at the University of Kansas.

Intra-rater correlations were calculated for the five areas. All three raters were above 0.93, with one exception; one rater had a intra-rater correlation of 0.84 of the callosal area.

Inter-rater correlations also indicated that the measures were consistent and reproducible: correlation for the corpus callosum area was 0.94 (average of the three Pearson's *r*); fourth ventricle, 0.96; cerebellum, 0.96; cerebrum, 0.97; cranium, 0.99.

Results

As seen in Table I, the two groups were not skewed in age distribution, and thus comparisons involving brain morphology between groups are valid. Also, there was no differences in results between the sexes by statistical analysis; thus, results (Table II) combine both sexes.

Using only brain areas, multivariate analysis of variance by Hotteling's t^2 was significant ($F=3.24$; $P<0.0106$). Univariate *t* tests were performed independently for each brain area measure (Table II). The results indicate that the fourth ventricle was significantly larger in the autistic group than in the control group. Cranium, cerebrum, and corpus callosum were not significantly different. The cerebellum was smaller in the autistic group, but the difference was not statistically significant.

Ratios were also analysed. Univariate *t*-tests revealed statistically significant differences for the fourth ventricle to cerebellum ratio (0.015±0.006 in the autistic group and 0.009±0.003 in the control group; $P<0.001$) and the fourth ventricle to cerebrum ratio (0.014±0.039 in the autistic group and 0.063±0.025 in the control group; $P<0.0002$). This indicates proportionally larger fourth ventricles in the autistic patients.

Discussion

Results of this study indicate that the MRI brain morphology of the autistic group was different from that of the control group. Specifically, on planimetrically analysed midsagittal MRI scans, the fourth ventricle of autistic children is larger than the same area of control children. The ratio of fourth ventricle to cerebrum also indicates that, proportionately, the fourth ventricle is larger in autistic children, and that the finding is not an artifact of larger brain size. Although there was a trend toward smaller cerebella in the autistic children, no other midsagittal areas measured differed statistically between autistic and control children.

Since this is a small sample size, the study needs replication not only with midsagittal views, but also with transverse and coronal images. However, if replicated, this finding, considered along with the autopsy and CT material, suggests strongly that the fourth ventricle is enlarged in autistic subjects.

The significance of an enlarged fourth ventricle finding is unclear. The fourth ventricle is related to the pons, cerebellum, and medulla. The midsagittal MRI scan images the ventricular length. This allows all portions of the fourth ventricle - inferior, middle, superior - to be seen. The superior portion of the fourth ventricle is bounded by the superior medullary velum and superior vermis in the roof, and the locus ceruleus and medial longitudinal fasciculus (MLF) of the upper pons in the floor. The middle fourth ventricle roof includes the cerebellar vermis and the central cerebellar nuclei; the floor of the middle part includes the MLF, and abducens (VI) and vestibulocochlear (VIII) nuclei. Finally, the inferior

Cranium	165.10 ± 14.77	170.23 ± 18.58

*Significant by *t*-test ($P < 0.002$).

medullary velum and the vermal nodulus define the roof of the inferior fourth ventricle, while the hypoglossal (XII) and vagal (X) nuclei, and MLF define the floor.

Of import are structures that have been implicated in autism, that define the fourth ventricle and, if altered, might alter the morphology of the ventricle. The central cerebellar nuclei have been reported to be aberrant in a neuropathological study of one 'autistic' brain (Bauman & Kemper, 1985). In another series of 'autistic' brains, there were widespread abnormalities in several cerebella (Ritvo *et al*, 1986). There are no anatomical studies of the brain stem to our knowledge. However, neurophysiological experiments suggest brain stem nuclei – especially areas in the pons (such as nucleus VIII) – are involved in autism (Ornitz, 1985). Thus, there is evidence that brain areas surrounding the fourth ventricle are involved with the clinical manifestations of autism; alterations in these discrete areas might then alter the space that they define, resulting in a relatively larger fourth ventricle.

Both brainstem and cerebellum have connections with, and affect function of, the limbic system, an area implicated in infantile autism. This suggests that widespread brain abnormalities, in neuronal circuits, are involved in autism. Although speculative, such abnormalities could be caused by aberrant development or early brain injury resulting in brain-tissue loss. Such brain-tissue loss would then result in the enlarged ventricular space.

This study indicates that in midsagittal MRI images, the fourth ventricle appears to be enlarged in autistic patients when compared with medical controls. This has several implications: replication is needed, with midsagittal and with other scanning orientations; and structures defining the fourth ventricle – the brainstem, the pons, and the cerebellum – deserve further morphological investigation in autism.

Substance-use Disorders in DSM–III–R

Evidence for the Dependence Syndrome Across Different Psychoactive Substances

THOMAS R. KOSTEN, BRUCE J. ROUNSAVILLE, THOMAS F. BABOR, ROBERT L. SPITZER and JANET B. W. WILLIAMS

Using the newly revised DSM–III–R criteria for substance-abuse diagnoses, we examined dependence syndrome elements among 83 psychiatric patients. The sample included 14 with no history of substance abuse. The remainder abused alcohol (52), sedatives (31), hallucinogens (12), stimulants (33), cannabis (44), cocaine (52), or opiates (47). Many patients (52) had abused more than one type of drug. Ten items assessing the proposed dependence symptoms for each type of drug were factor-analysed. The dependence syndrome items formed a single factor for opiates, cocaine, and alcohol, but not for other drugs. When the items were combined into cumulative scales, they had excellent internal consistency. Furthermore, they formed good approximations of unidimensional Guttman scales on which higher scores indicated greater syndrome severity. The items associated with higher scores differed across drugs, with opiates having the most striking differences from the other substances. Medical-psychosocial consequences were relatively independent of the dependence syndrome, although alcohol and cocaine dependence had some association with other problem areas. These findings support the utility of a common dependence syndrome concept for drugs of abuse as well as alcohol, and provide empirical support for the current revision of the DSM–III diagnostic criteria.

The alcohol-dependence syndrome concept, proposed in 1976 by Edwards & Gross (1976), has stimulated considerable interest in the alcoholism field as evidenced by the development of six different scales measuring syndrome elements and a number of empirical studies providing support for the construct (Orford *et al*, 1976; Litman *et al*, 1979; Stockwell *et al*, 1979; Chick, 1980; Polich *et al*, 1981; Skinner & Allen, 1982; Heather *et al*, 1983; Hesselbrock *et al*, 1983; Foy *et al*, 1984; Edwards, 1986). Within the context of the ongoing work of the World Health Organization (WHO) on nomenclature and classification of alcohol- and drug-related problems, the syndrome construct, hypothesised initially only for alcoholism, has been broadened to apply to other psychoactive substances and is part of the proposed diagnostic criteria for psychoactive substance use disorders in the 1986 draft of the International Classification of Diseases (ICD–10) (Edwards *et al*, 1981; Kendell *et al*, 1986). As articulated in a WHO memorandum (Edwards *et al*, 1981) the drug-dependence syndrome includes two testable postulates about other types of drug dependence: unidimensionality of the syndrome elements and independence of the syndrome from consequences. Unidimensionality means that the syndrome is manifested by the clustering of certain elements to form a single dimension, and since the syndrome is not all-or-none but dimensional, with increasing severity a substance abuser manifests more of its elements. Statistical unidimensionality results from relatively uniform levels of intercorrelation among the items or symptoms within the syndrome and can be assessed by factor analysis and by various measures of internal consistency for the syndrome scale. Independence of the syndrome means that the dependence syndrome constitutes one axis of drug problems, and other problems related to substance abuse, such as legal, occupational, and family consequences of drug use, form a separate, relatively independent axis. Thus, a patient with many or most symptoms of the dependence syndrome would not necessarily have severe legal or family problems, for example, and conversely, a patient with few syndrome elements might have many other severe problems.

In revising the American Psychiatric Association's *Diagnostic and Statistical Manual*, third edition, and in the proposed ICD–10, several major changes have been made in the criteria for substance-use disorders which make this diagnostic system more reflective of the hypothesised dependence syndrome (Kendell

TABLE I

Relationship of DMS-III-R substance-dependence criteria to WHO drug-dependence syndrome elements

	DSM-III-R criteria	*Dependence syndrome elements*
1.	Repeated effort or persistent desire to cut down or control substance use.	Readdiction liability
2.	Often intoxicated or impaired by substance use when expected to fulfil social or occupational obligations or when substance use is a hazard (e.g. goes to work high, drives when drunk).	Salience
3.	Tolerance: need for increased amounts of substance in order to achieve intoxication or desired effect, or diminished effect with continued use of same amount.	Tolerance
4.	Withdrawal: substance-specific syndrome following cessation or reduction of intake of substance.	Withdrawal
5.	Frequent preoccupation with seeking or taking the substance.	Compulsion
6.	Has given up some important social, occupational, or recreational activity in order to seek or take the substance.	Salience
7.	Often uses a psychoactive substance to relieve or avoid withdrawal symptoms (e.g. takes a drink or diazepam to relieve morning shakes).	Withdrawal avoidance
8.	Often takes the substance in larger doses or over a longer period than he or she intended.	Compulsion
9.	Continuation of substance use despite a physical or mental disorder or a significant social or legal problem that the individual knows is exacerbated by the use of the substance.	Salience
—	Reinstatement of excessive substance use after a period of abstinence is much more rapid than initial development. (Dropped from final DSM-III-R.)	Readdiction liability
—	Not represented in DSM-III-R.	Narrowing of repertoire

et al, 1986; Rounsaville *et al*, 1986). The revised DSM-III criteria are described in Table I along with the corresponding elements of the WHO drug-dependence syndrome. The elements hypothesised as clustering together in the dependence syndrome are the following: (a) narrowing of substance-use repertoire such that substance use becomes stereotyped around a regular schedule of almost continuous or daily consumption; (b) salience of substance-taking behaviour such that, despite negative consequences, substance use is given higher priority than other activities which had previously been important; (c) increased tolerance; (d) withdrawal symptoms; (e) substance use to avoid withdrawal; (f) subjectively experienced compulsion to use substance; and (g) readdiction liability (Edwards & Gross 1976; Edwards *et al*, 1981). Because several items have been used to tap some of these dependence elements, the DSM-III criteria include ten, rather than seven, items.

Purpose of the present study

In the current study, the Substance Dependence section of the Structured Clinical Interview for DSM-III (SCID) (Spitzer & Williams, 1985; Rounsaville *et al*, 1986) was used to measure dependence syndrome elements. Two settings were included: (a) an out-patient substance-abuse treatment unit, chosen for the high prevalence of individuals likely to receive a substance-abuse diagnosis, and (b) an in-patient psychiatric unit, in which substance-abuse is seldom the primary focus of treatment, chosen in order to test the system's ability to discriminate between those with and without a substance-use disorder. In the current report, data are analysed to assess the validity of the drug-dependence syndrome as it applies to use of both alcohol and other substances of abuse. To the extent that the dependence syndrome is shown to be valid for a range of substances, this would provide empirical support both for the dependence syndrome construct and for its inclusion in the DSM-III-R and ICD-10.

Two postulates of the dependence syndrome were evaluated: (a) the prediction that syndrome elements cluster into a unidimensional scale, and (b) the relative independence of this syndrome from legal, occupational, medical, family, and psychological problems associated with substance use. To evaluate the clustering of dependence syndrome elements into a unidimensional scale, the ten items pertaining to each substance were assessed for internal consistency using item-scale correlations and by the formation of Guttman scales for each type of drug. The ten items for each drug were also factor-analysed. The syndrome scales were correlated with measures of consequences from the Addiction Severity Index to assess their relative independence.

Method

Setting and sample

Subjects were interviewed at two settings: (a) 41 patients from an in-patient unit of a community mental-health centre, which treats patients with a wide range of diagnoses for 28 days, and (b) 42 patients applying for treatment at an ambulatory substance-abuse treatment unit. In both settings, patients were interviewed as a sample of convenience, when the interviewers were available. For the in-patient unit, the sample was predominantly male (54%), white (51%), with a high school education or more (80%) and with an average age of 34 (s.d. 10 years). For the out-patient setting, the sample was predominantly male (74%), white (62%), with a high-school education or more (81%) and with an average age of 29 (s.d. 7 years). Thus, both samples were demographically comparable.

The patients were also assigned DSM-III diagnoses using the Diagnostic Interview Schedule (DIS), as described in a companion paper (Rounsaville *et al*, 1987). Percentages of in-patients meeting DSM-III criteria (American Psychiatric Association, 1980) for substance abuse or dependence were as follows: alcohol 44%; sedatives 20%; cannabis 24%; stimulants 15%; opioids 34%; cocaine 22%; and hallucinogens 2%. The rates of out-patients meeting abuse or dependence on substances according to DSM-III criteria were as follows: alcohol 55%; sedatives 14%; cannabis 14%; stimulants 14%; opioids 64%; cocaine 74%; and hallucinogens 2%. As anticipated, the rates of substance-use disorders were considerably higher in the out-patient sample who identified themselves as substance abusers by seeking specialised treatment.

Although 14 subjects had no history of drug abuse and 17 reported abuse of only one type of drug, many subjects reported abusing more than one drug. The mean number of drugs abused was 2.3. The three most common combinations were cocaine and alcohol (25 patients), cocaine and opiates (24 patients), and opiates and alcohol (20 patients). Eleven patients reported abuse of all three – cocaine, opiates and alcohol – and two of these reported abuse of all seven types of drug. Other drug combinations were less common, except for cannabis with cocaine (19 patients) and cannabis with alcohol (17 patients). To evaluate the clustering of dependence-syndrome elements and to evaluate their relationship to substance-related consequences, the data from the two samples were first evaluated separately and found to be nearly identical. Hence, for economy of presentation, only the results from the combined samples will be presented here.

Instruments

Two instruments were employed in the present study: (a) the Substance Dependence Disorders section of the Structured Clinical Interview for DSM-III (SCID) (Spitzer & Williams, 1985), and (b) the Addiction Severity Index (McLellan *et al*, 1980; Kosten *et al*, 1983). The SCID is designed to be used by clinicians and provides an interview guide for determining whether subjects meet DSM-III-R criteria for a range of psychiatric disorders. Two graduate-level clinicians conducted all interviews for the present study. For each criterion, which is rated as absent, subthreshold, or prototypical, the interviewer is provided with one or more questions which are read out. If the subject's response is positive or unclear, the interviewer is instructed to continue inquiry using questions of his/her choice in order to elicit examples and confirm the subject's initial response. The SCID is designed to elicit symptoms of current and/or past episodes of psychiatric disorders. For the Substance Dependence section used for the current study, subjects were asked to describe substance use during the most severe episode in their lifetime, regardless of the presence or absence of a current episode.

The version of the SCID used in this study contained an additional DSM-III-R criterion which was subsequently dropped from the final DSM-III-R. This criterion defined the syndrome characteristic of 'readdiction liability' by the statement, "Reinstatement of excessive substance use after a period of abstinence is much more rapid than initial development." The criterion was dropped from DSM-III-R because it presupposed a pattern of excessive substance use and was considered to be a hypothetical characteristic of the entire syndrome rather than an element of it. Because the primary purpose of the current report is to evaluate the drug-dependence syndrome in this sample, we included this additional criterion despite its having been eliminated from DSM-III-R.

The Addiction Severity Index (ASI) was also completed for all in-patients (one had incomplete data) and a pilot sample of 15 of the 43 out-patients. The ASI is a clinician-administered instrument that covers six major problem areas: legal, employment, medical, family, psychological, and substance abuse (McLellan *et al*, 1980; Kosten *et al*, 1983). Composite scales involving several items in each area have been developed to reflect current functioning. The five non-substance-abuse scales were related to the dependence-syndrome elements to examine the relative independence of these consequences from the dependence syndrome (Edwards *et al*, 1981). The 28 out-patients who did not complete the ASI were similar to the remaining patients in demographics and in the frequencies of substance-abuse diagnoses.

Data analyses

The unidimensionality of the dependence syndrome elements was examined using three related techniques: item–scale correlations, Guttman scaling and factor analysis. The item–scale correlations and the Guttman scaling used the ten dependence items from the SCID interview to develop scales to measure the dependence syndrome. The Guttman scaling was attempted with all ten dependence items shown in Table I, in order to examine whether some syndrome elements were common and likely to occur in isolation (low Guttman scores), while other elements were primarily reported by patients with the full-blown syndrome (high Guttman scores). In using Guttman analyses the usual reproducibility coefficient for an acceptable 'perfect' Guttman scale is 0.9. If the coefficients are substantially below this level, the cumulative scores and sequence of high-scoring (frequent) and low-scoring (rare) items will be unreliable (Guttman, 1944). A good fit of the items to a Guttman scale suggests that the cumulative scores formed by adding all the items together, when scored as 0 for absent and 1 for present, were reasonable estimates for the severity of the dependence syndrome. Comparing mean scale scores for abusers, as well as the specific dependence items associated with high and low Guttman scores, across different substances allowed us to examine how the dependence syndrome differed among various drugs. Factor analyses were also performed on the ten dependence items for each drug. When more than one factor had an eigenvalue above 1 by the initial principal components extraction, a varimax rotation was undertaken for all factors with eigenvalues greater than 1. After these dependence syndrome scales were examined for unidimensionality, the dependence scales and the five composite scales from the ASI were correlated to check for independence of the dependence syndrome from these other problem areas.

Results

Internal consistency of dependence syndrome across drugs

The dependence syndrome items were scored as 0 for not present and 1 for subthreshold or prototypical and then added together for each drug type to form seven dependence syndrome scales with scores ranging from 0 to 10. The prototypical and subthreshold ratings were combined to simplify scaling and because subthreshold ratings were rarely made in our sample. The mean scores on these scales for the subjects reporting any of these items, and the number of subjects represented in each mean are shown in Table II, along with two measures of internal consistency - item-scale correlations and Cronbach's alpha. The values for Cronbach's alpha (Cronbach & Furby, 1970) indicated excellent internal consistency for all seven scales, and the item-scale correlations were quite good overall. All item-scale correlations were above 0.5 except for three items in the sedative scale (preoccupation, continue despite problems, and impaired in daily activity), one hallucinogen item (rapid restart of use), and three cannabis items (relief use, withdrawal, and tolerance). The mean scores show that opiate addicts reported the largest number of dependence syndrome elements and had the tightest clustering of these items, while sedative and cannabis abusers reported the fewest syndrome elements. We examined this difference in more detail by studying the distribution of number of items reported for each drug among those patients who reported any dependence syndrome items for each of the seven drugs.

As shown in Table III, item distributions of sedatives, hallucinogens, and cannabis are negatively skewed, with few patients (3–8%) reporting large numbers of syndrome items (8–10 items). In contrast, the distribution of cocaine and opiates are positively skewed, with many patients reporting large numbers of items (48% and 72%, respectively). Furthermore, 27% of the cocaine abusers and 49% of the opiate addicts reported all ten of the dependence syndrome

TABLE II

Item–scale correlations, Cronbach's alpha, and mean scale scores on dependence syndrome items for each drug of abuse (n = 83)

Mean scores[2] for users only	5.6	3.3	3.7	4.3	3.3	6.9	8.0
Number abusing each drug type	52	31	12	33	44	52	47

1. Cronbach's alpha >0.8 shows excellent internal consistency.
2. Scores ranged from 0 to 10, items scored as 0 = no, 1 = yes. Mean scores only for subjects reporting use of that drug

TABLE III
Number of dependence syndrome items reported for each drug of abuse (n = 83)

	Number of items										
Drug of abuse	*0*	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*
Alcohol	31	4	4	7	7	4	3	5	9	5	4
Sedatives	52	8	8	3	2	3	4	2	0	1	0
Hallucinogens	70	3	3	2	1	0	0	1	0	0	1
Stimulants	50	5	7	3	7	2	2	0	2	3	2
Cannabis	39	12	9	6	5	5	3	2	1	0	1
Cocaine	31	3	2	6	1	6	3	6	4	7	4
Opiates	36	2	4	1	1	1	1	3	4	7	23

items. By comparison, 35% of the alcohol users reported large numbers of items. Stimulant users had an intermediate position, with 21% of them reporting large numbers of items. Thus, opiate and cocaine abusers who apply for treatment have a substantial clustering of dependence-syndrome elements, similar to alcohol abusers, but typical sedative, cannabis, and hallucinogen abusers appear to have fewer syndrome elements.

Unidimensionality of dependence syndrome

The above analyses for internal consistency strongly suggested that the ten dependence-syndrome items formed cumulative, unidimensional scales, particularly for opiates, cocaine, and alcohol. As a test of unidimensionality, we attempted to form Guttman scales for each type of drug from the ten items. The results of these analyses are shown in Table IV. As indicated by the reproducibility coefficients, most of the drugs demonstrated good approximations of 'perfectly' unidimensional and cumulative scales. The coefficients were 0.9 or above for all but two drugs – alcohol and cannabis – and these two coefficients were close to 0.9 (0.85 and 0.87, respectively). This indicated that within each type of drug, higher scores were consistent with a more severe dependence syndrome, but the items associated with a more severe syndrome differed across the various drugs. The most striking differences were between opiates and the other drugs. For example, opiate abusers reporting "withdrawal symptoms" almost always reported every other item of the dependence syndrome (score of 10), but abusers of other types of substance often reported this item with few or no other dependence-syndrome items (score of 1–3). At the other extreme, opiate abusers often reported "using more opiates than they intended" along with few or no other dependence-syndrome items (score of 3), but abusers of other types of substance usually reported this item in conjunction with most other items in the syndrome (score of 8–10).

To test further for unidimensionality, we factor-analysed the ten items within each type of drug and found that all ten items loaded on to single factors for opiates, cocaine, and alcohol, as shown in Table V. These single factors accounted for a substantial part of the variance: 83% for opiates, 68% for cocaine, and 56% for alcohol. Obtaining these single factors suggested unidimensionality, that is, endorsing more items was consistent with the unitary concept of more severe drug dependence. Stimulants formed two factors that accounted for 67% of the variance. The factors were labelled "compulsion" and "problematic use", based on the items loading above 0.5. Sedatives and cannabis each had three factors with eigenvalues above 1. Based on the items loading on each factor, two common factors were labelled "can't stop" and "compulsion/salience". The other factor was different for the two drugs and was labelled "problematic use" for sedatives and "withdrawal consequences" for cannabis. The three factors accounted for 69% (sedatives) and 68% (cannabis) of the variance. Because five of the hallucinogen dependence syndrome items were reported by less than four respondents,

TABLE IV
Guttman scale scores[1] using dependence-syndrome items for each drug of abuse (n = 83)

TABLE VI

Correlations between dependence syndrome scales[1] *and Addiction Severity Index problem severity scores*[2] *for each drug of abuse* ($n=55$)

ASI problem severity scores	*Alcohol*	*Sedatives*	*Hallucinogens*	*Stimulants*	*Cannabis*	*Cocaine*	*Opiates*
	Drug of abuse						
Medical	0.07	0.12	−0.23	−0.08	−0.19	−0.01	0.09
Work	0.14	0.08	−0.29*	−0.10	−0.11	−0.32*	0.12
Legal	−0.12	0.23	0.07	0.21	0.26	0.46***	0.03
Family	0.29*	0.10	−0.05	−0.01	−0.15	0.03	0.13
Psychological	0.32*	0.10	−0.25	−0.06	−0.13	−0.13	−0.12

1. Dependence scale is additive score from the ten dependence syndrome items for each type of drug, scores range from 0 to 10, with higher scores indicating more dependence syndrome items reported; See Tables II and III.
2. Problem scales from ASI are composites of self-report items on which higher scores indicate more severe problems; scores range as follows: legal (−0.01 to 0.18), work (−0.5 to 0), medical (0 to 0.33), family (−0.06 to 0.16), psychological (0.33 to 1.0).

*$P<0.05$, ***$P<0.0005$.

these infrequent items were removed. Including all ten items resulted in three factors, of which one included all five infrequent items. When these items (indicated by * in Table V) were deleted, the other five items loaded together as a single factor that accounted for 69% of the variance.

Independence of dependence syndrome from drug-use consequences

The dependence syndrome was quantified for each drug type using a simple additive scale including all ten items, as described above, and these seven dependence syndrome scales were correlated with five composite problem severity scales from the ASI: legal, work, medical, family, and psychological. Higher scores on these ASI scales indicated more severe problems in each area. The mean scores (± standard deviations) on these five ASI scales were: legal 0.06(±0.05), work −0.12(±0.18), medical 0.09(±0.10), family 0.02(±0.07), psychological 0.74(±0.17). As shown in Table VI, five of the 28 correlations between the seven dependence scales and the ASI scales were significant, and this is more than expected by chance alone. The alcohol-dependence scale correlated with family problems ($r=0.29$, $P<0.04$) and psychological problems ($r=0.32$, $P<0.02$); the cocaine dependence scale correlated with legal problems ($r=0.46$, $P<0.0004$) and work problems ($r=-0.32$, $P<0.02$); and the hallucinogen dependence scale correlated with work problems ($r=-0.29$, $P<0.04$). Overall, however, the ASI scales were relatively independent of the dependence syndrome scales, and even for significant associations the shared variance was small.

Discussion

Is the dependence syndrome valid for all drugs?

This study is a first systematic psychometric examination of the dependence syndrome among abusers of non-alcoholic substances. Based on the newly revised DSM-III-R substance-abuse criteria (Rounsaville *et al*, 1986), we found that the ten items in the draft form of the SCID formed internally consistent scales for all seven drugs under study. For alcohol, opiate, and cocaine abusers the dependence syndrome scale met several criteria for unidimensionality, including all items loading on to a single factor, and forming good approximations to 'perfect' Guttman scales. For the other drugs – stimulants, sedatives, hallucinogens, and cannabis – a clear unidimensional structure was not confirmed by every type of analysis, but even for these drugs, simple cumulative scales seemed to provide satisfactory measures of a dependence syndrome that was independent of medical–psychosocial problems. However, these problems were somewhat related to the dependence syndrome for alcohol and cocaine. Thus, our findings supported the utility of the dependence syndrome for other drugs besides alcohol by specifically demonstrating that the syndrome elements clustered into unidimensional scales for most drugs and that this syndrome was relatively independent of medical–psychosocial problems.

The different types of statistical analysis used to test for unidimensionality of the dependence syndrome were not consistent for all seven drugs of abuse. The simplest tests using raw correlations among items suggested that several items did not substantially contribute to a simple dependence-syndrome scale for every drug. These low contributors differed among the seven drugs, but for most drugs each item was an important contributor. Based on these statistical analyses, no particular item seemed to merit deletion in order to improve internal consistency over all seven drug types. Even when the low contributors were included in a total cumulative scale, we found excellent scale properties according to coefficient alpha, and the mean scale scores were consistent with the item–scale correlations. Scales with high intercorrelations (e.g. opiates) also had high mean scores for the abusers of this drug, because those subjects who reported one item were also likely to report most other items. Scales with lower intercorrelations (e.g. sedatives) had lower mean scores, because abusers of these drugs tended to more frequently report only a few items. Thus, the inconsistencies with unidimensionality seemed minor using simple statistical approaches.

These correlational results encouraged the examination of a stronger model for unidimensionality, Guttman scaling. The good fit of these items to Guttman scales suggested that the cumulative scores were reasonable approximations of severity for the dependence syndrome, allowing us to systematically compare relative severity of dependence across drugs. Among the users of each type of drug, opiates were associated with the most severe dependence and cannabis with the least dependence. This is consistent with general clinical experience for substance abusers and gives further support to this new system for classifying substance abuse. Moreover, polydrug use was common in our samples, and patients who used several drugs during their lives consistently rated opiates and cocaine as more severe problems than cannabis or sedatives. In general, all seven scales appeared to be good unidimensional measures of dependence, in which higher scores indicated more severe dependence.

Comparing frequent to uncommon items within these scales suggested which elements of the syndrome were likely to occur early (frequent items) or late (uncommon items) in the substance-dependence careers of the various types of abuser. Among alcoholics and most other abusers, withdrawal, and "preoccupation with use" were frequent and probably early elements, but these occurred less frequently and were probably later elements among the opiate addicts. This sequence difference among opiate addicts may simply be an artifact of the large percentage of opiate addicts who reported every dependence item, but it is also consistent with the 'chipping' described by most opiate addicts at the start of their careers. Chipping addicts do not get withdrawal symptoms and are not yet preoccupied with getting their next 'fix' of heroin (Chein *et al*, 1964). In contrast, alcohol use is usually not considered a problem until some type of at least mild withdrawal symptoms begin occurring, and the same may be true for cannabis (Litman *et al*, 1979; Marlatt & Gordon, 1980). For cocaine abusers, a 'crash' is commonly described, even following limited recreational use (Gawin & Kleber, 1986), and this crash may be reported as withdrawal symptoms. At the other extreme, many opiate addicts reported "using more than intended" early in their careers. The relatively frequent occurrence of accidental overdoses with opiates compared with accidental overdoses of the other drugs may be an extreme clinical manifestation of this difference, but otherwise there seems no obvious reason why opiate abusers might not share this early characteristic with other illicit drug abusers such as cocaine abusers. Moreover, opiate abusers appeared to be atypical in their development of the dependence syndrome, although they had the strongest support for a coherent syndrome.

The factor analyses of the ten items for each drug raised the most significant questions about the unidimensionality of the dependence syndrome for stimulants, sedatives, and cannabis. For hallucinogens, the separation into three factors seemed partially due to low-frequency items that reflected idiosyncratic responses to hallucinogens, such as withdrawal symptoms. After these items were dropped, the remainder loaded on to a single factor. Although a compulsion factor was formed for stimulants, sedatives, and cannabis, its content was not uniform across the three drugs and these analyses did not support a unidimensional dependence syndrome. The biaxial concept of Edwards *et al* (1981) that dependence may be relatively independent of social consequences was given some support by the "problematic-use" factors for stimulants and sedatives, because the items in these factors reflect social consequences of abuse. Moreover, the single factors that were found for alcohol, cocaine, and opiates demonstrated more coherence among the dependence-syndrome elements than other studies have found for alcohol abuse (Edwards, 1986). In summary, the status of the dependence syndrome for stimulants, sedatives, and cannabis needs further work with larger samples, but based on the other internal reliability analyses we decided to use simple additive scales for all seven drugs as a dependence syndrome axis to examine the postulate that the dependence syndrome was relatively independent of 'drug-related problems'.

The correlations of the dependence syndrome with consequences clearly indicated that many problem areas were relatively independent of the dependence syndrome. The strongest association was between the cocaine dependence syndrome scale and legal problems, and it may reflect the need for increased amounts of illegal activities as the abuser becomes more 'dependent' on the drug. In support of this argument, the only licit substance – alcohol – demonstrated a negative correlation with legal problems, while for all the other drugs the correlations were positive. Other significant correlations accounted for less than 10% of the variance and were inconsistent across drugs, suggesting the need for confirmation before being overinterpreted.

Study limitations

This preliminary study has several limitations. First, the sample size is small and limited to one treatment centre, although it included both in-patients and out-patients as well as subjects who were not substance-abusers. These non-abusers assured that the correlational analyses using the dependence syndrome scales were not biased by limited variability, although the large number of non-abusers for some drugs such as hallucinogens would overstate the tendency for a single syndrome to fall out from the factor analyses. Future studies will need larger samples, perhaps from different cultural settings. Second, these subjects had all sought treatment, and this self-selection bias may need to be addressed through community studies. Third, the ASI was designed to assess both lifetime and current (last 30 days) problems, but the SCID was administered to reflect the period of most intense substance abuse. For the vast majority of these subjects, the current episode of abuse was their most severe, but for hallucinogens, in particular, many of the subjects were not currently experiencing their most severe abuse. Relatively few subjects also reported hallucinogen abuse, and so any interpretations of these findings must be quite tentative. Future studies will need to be designed to have better correspondence between time frames for the dependence-syndrome assessments and the psychosocial measures. Fourth, some subjects had abused more than one drug. The most frequent combinations were opiates with cocaine, and alcohol with cocaine. Using 'pure' drug-abusers would facilitate interpretations across the different drugs, but this is practically impossible in most current treatment programmes, in which abuse of more than one drug is common (Simpson & Sells, 1974; Hubbard *et al*, 1983).

Conclusion

The present study provides encouragement for undertaking more intensive work with other substances besides alcohol using the newly revised DSM-III-R.

Brief Reports

Conversive Hallucinations

Conversive hallucinations are rare in the psychiatric literature. The authors present a case which demonstrates the psychogenesis and phenomenology of conversive hallucinations in a young female patient.

Hallucinations are usually considered to be psychotic in nature. Conversive hallucinations are very rare. Nemiah (1980) stated that they are rare and usually visual in nature, and are of complex scenes of fragments of action that appear repeatedly and with stereotyped repetition after reproducing the scenes of a real past event of emotional significance to the patient. Farley *et al* (1968) defined conversive symptoms as "neurological symptoms (excluding pain) which are clinically inexplicable". They have reported that the hallucinations occurred as conversive symptoms in 12 of 100 unselected post partum cases. Hirsch & Hollender (1969) described conversive hallucinations in hysterical states. Levinson (1966) reported on an hysterical patient who had auditory hallucinations. McKegney (1967) described two cases of auditory hallucinations as a conversive symptom. Fitzgerald & Wells (1977) described a complex of visual and auditory hallucinations in a young woman as a conversive reaction. Modai *et al* (1980) reported on conversive hallucinations, visual and auditory in nature. Andrade & Srinath (1986) reported on true auditory hallucinations as a conversive symptom in a 10-year-old girl.

Case report

Mrs H – a 28-year-old woman, born in Israel, of Iraqi origin, married and mother of three children – was admitted to Geha Psychiatric Hospital, Israel, because of increased psychomotor activity and visual and auditory hallucinations. She was the third of eight children. The domestic atmosphere was very difficult and tense. She worked in various jobs from the age of 10 years, when her studies stopped. She never felt well at home, and at the age of 15 years she left home and married a 21-year-old man, a delinquent and drug addict without permanent occupation. She gave birth to three daughters. The family lived on welfare funds and Mrs H worked from time to time as a cleaning woman. Her husband was put in jail for long periods for drug-pushing. Mrs H was left alone to cope with the hard reality. While he was at home, her husband exhibited violent behaviour towards his wife and daughters. Despite the constantly deteriorating relationship, she refused to divorce him.

A week before her admission, her husband was discharged from jail and demanded that she give him money for drugs. Mrs H reacted to this demand with increased anxiety, lay in bed, refused to eat or talk, and became restless every time someone tried to contact her. At this stage she was admitted to our psychiatric ward.

On admission, her restlessness, apprehensiveness, anxious affect, and visual and auditory hallucinations were prominent. Her consciousness was clear and her temporal and spatial orientation were intact. She did not exhibit any delusions. The auditory hallucinations were peoples' voices in her ear that prohibited her to eat and talk and threatened to murder her if she talked to anyone. The visual hallucinations were composed of tiny monsters having a human body without a definite colour, very figuratively, that appeared while her eyes were closed at a distance of 5–6 m. Their appearance and disappearance was sudden and they frightened her very much. The hallucinations were tension and spatial-dependent: they appeared only at her home in the presence of her husband. She had insight that the hallucinations were not real. Her physical examination was intact. Her laboratory tests were within normal range. Her electroencephalograph and computerised tomography of the brain were normal.

The patient was diagnosed as having a histrionic personality disorder with conversive hallucinations. This diagnosis was based on her overly dramatic and intensely expressed behaviour, as manifested by exaggerated expression of emotions, incessant drawing of attention to herself and overreaction to minor events, egocentricity, demanding, and dependence and constant seeking of reassurance. She was treated with diazepam 5 mg t.i.d. and psychotherapy.

Twelve hours after her admission the tension, anxiety, and hallucinations disappeared and she resumed her normal level of functioning. After several days she went home for a short time, and the hallucinations recurred at night with the same characteristics as described above. She was brought back to the hospital and as she entered the ward she calmed down and the hallucinations disappeared. During her stay in hospital, together with the individual psychotherapy she and her husband were treated with couple psychotherapy. She was discharged after six weeks in a good remission. At six-month follow-up the hallucinations had not reappeared.

Discussion

Mrs H suffered from two types of hallucinations, namely visual and auditory, while awake. Her visual hallucinations were very primitive and naive. Visual hallucinations of this type, not real, that appear in the inner subjective space out of the dark fields of the eyes with a sense of distance, and suddenly appear and disappear, might be termed pseudo-hallucinations according to Kandinsky, as cited by Jaspers (1963).

These hallucinations had frightened Mrs H, who was in a state of permanent anxiety because of her husband's threatening and her incompetence to cope with his violent behaviour. The hallucinations were an expression of her ambivalent projected aggression towards her husband, a feeling and attitude that were very prominent in her from childhood, when the object of this ambivalence was her father. Her aggressive drives towards her husband and her desire to get rid of him were suppressed by very deep guilt feelings and a fear of being punished for these drives and prohibited wishes. In this way she was able to escape from guilt feelings and at the same time to express her aggression towards him. Using Engel's criteria (1970), this patient was expressing clinically a conversive phenomenon. Engel described four targets of the conversive symptom:

(a) allowing the expression of prohibited wishes (in our case it was a wish to escape from punishment because of her deep guilt feelings);
(b) punishment through guilt feelings (the patient punished herself by becoming ill and suffering from frightening hallucinations);
(c) avoidance of a threatening situation (Mrs H's detention in hospital let her run away, at least temporarily, from coping with her husband's behaviour and attitude toward her);
(d) accepting the sick role (and indeed she received a new role – that of a psychiatric patient).

We can see that our patient had expressed through the conversive hallucinations all four of Engel's criteria. The symptoms originated as a consequence of psychological stress and their appearance offered the patient an escape from a life-threatening situation. Freud (1948) wrote: "flight from a disturbing life situation could take the form of wish-fulfilling delusions and hallucinations". Our patient fits to this statement by her symptoms as described above.

Hirsch & Hollender (1969) stated that a person in a state of extreme anxiety can lose his ability to react promptly to a situation and at this point symptoms like hallucinations can appear.

The only solution which was left for our patient was the production of a conversive symptom, and through it to change the role of a wife and mother for that of the invalid.

Usually the conversive symptom serves a primary gain and a secondary gain. Mrs H's primary gain was preventing the severe anxiety which resulted from unresolved aggressive and sexual conflicts. The secondary gain was running away from a life-threatening situation at home, being detained in hospital and treated as a psychiatric patient, and developing a dependency on the medical and nursing personnel and through it gaining protection and security.

In discussing this case we have to discuss the concepts of hysterical psychosis, culturally sanctioned psychoses, and acute paranoid reaction (boufée delirante). Merskey (1979) wrote that hysterical psychosis is a debatable concept. 'Hysterical insanity' was used by Kraepelin (1904) for severe prolonged hysterical symptoms without delusions or hallucinations being present. 'Hysterical psychosis' was used by Breuer & Freud (1893–1895) in a more usual way, but Bleuler (1950) and Reichard (1956) criticised the term; it was, however, revived by Hollender & Hirsch (1964) for psychotic symptoms of sudden onset and brief duration, arising in patients with hysterical personalities after a period of increasing stress. The symptoms included delusions, hallucinations, depersonalisation, and grossly unusual behaviour, and usually lasted 1–3 weeks.

Mallet & Gold (1964) described 13 patients, all women, that at some point had been diagnosed as schizophrenic because of unsuccessful treatment, emotional emptiness and bizarre depersonalisation, phenomena, paranoid ideation, and dramatic visual and auditory hallucinations. All the patients displayed hysterical personality traits. In every case, admission to hospital followed an acute episode of violent or negativistic and symbolic behaviour or a suicidal attempt. (Five of the patients ultimately committed suicide.)

Hirsch & Hollender (1969) suggested that the illness might present in three ways:

(a) as socio-culturally sanctioned behaviour
(b) as simulation of psychotic behaviour
(c) as a true psychosis with temporary ego disruption and impairment of repression.

Siomopoulos (1971) considers that the delusional ideas in hysterical psychosis lack the characteristics of incorrigibility, which is an essential feature of the delusion proper. The patient described by us differs from the hysterical psychotic patients described above in that she lacked delusions, depersonalisation, and grossly disturbed behaviour. The hallucinations were spatial-dependent and she had insight that they were not real. All these characteristics excluded the diagnosis of hysterical psychosis.

The differential diagnosis of our case should include culture-bound or exotic syndromes. The first are what Hirsch & Hollender (1969) noted where a cultural practice sanctions extreme behaviour. Other examples include latah, ainu, amok, piblokto, wihtigo, voodo and phii pob, all of which are described by Merskey (1979). Allodi (1982) stated that many of the exotic conditions are regarded now as the equivalent of hysterical, obsessional, and anxiety syndromes in which there may be a partial or transient withdrawal from reality; they have been ascribed to the idiosyncratic ego organisation of people living in rural or pre-technological societies and to the conditions prevalent in those cultures. These types of behaviour are determined by the prevailing belief system of the given culture. In contrast to this essential feature, our patient's behaviour as described above was determined far more by individual dynamics than by the prevailing belief system of our culture, or social considerations.

The last entity to be differentiated is the acute paranoid reaction studied by Allodi (1982), named also bouffée delirante in the French literature and psychogenic psychosis in the Scandinavian literature. This diagnosis refers to a subcategory of reactive or other non-organic psychoses which reportedly occurs frequently among immigrants, refugees, and other groups subjected to major social stress. Our patient does not fit this diagnosis because she lacked delusions, had good insight into her hallucinations, did not lose reality-testing, did not have rapid switches from elation to depression, and was not a new immigrant or refugee.

We would like to close this discussion with a quotation from Merskey (1979): "culturally sanctioned behavior, simulation of psychosis, reinforcement of repression, and gross regressive behavior occur in a variable mixture in different syndromes. It is easier to understand these illnesses than to group them systematically."

The authors suggest that psychogenesis and phenomenology of this type in a non-psychotic and non-dissociative patient represent conversive hallucinations and are similar to the descriptions of Fitzgerald and Modai. In the background of these hallucinations were repressed aggressive and libidinal drives that could not be expressed in the patient's daily life with her husband. Only via the conversive hallucinations she was able to express them deliberately. The appearance of hallucinations in the clinical symptomatology does not imply a psychotic state, and the clinician should bear in mind that they can reflect a conversive phenomenon.

Lithium Toxicity and Mefenamic Acid

A Possible Interaction and the Role of Prostaglandin Inhibition

An elderly patient with bipolar manic-depressive psychosis, stabilised satisfactorily on lithium carbonate, developed acute symptoms of lithium toxicity shortly after commencing mefenamic acid. Vulnerability factors for the interaction may have included age, history of cardiac failure, and impaired glomerular function. It is hypothesised that the interaction may have been mediated by inhibition of prostaglandin activity.

Non-steroidal anti-inflammatory drugs (NSAIDs), such as indomethacin, diclofenac, ibuprofen, and piroxicam, have been suggested to increase serum lithium levels (e.g. Reimann *et al*, 1983). The mechanism of the effect is unclear. This report is the first of a possible interaction between lithium and the NSAID mefenamic acid (Ponstan), which resulted in a clinical syndrome of lithium toxicity. Moreover, it considers the putative role of prostaglandin inhibition in the interaction.

Mefenamic acid is effective in the treatment of pain. Its mode of action appears to be through inhibition of prostaglandin synthesis or possibly through prostaglandin receptor antagonism. Reported adverse side-effects have included non-oliguric renal failure. None has involved lithium carbonate, a drug which is excreted almost exclusively by the kidney.

Case report

Interaction between mefenamic acid and lithium occurred in a 62-year-old female who had a 12-year history of bipolar manic–depressive psychosis. She had been maintained well for seven years on lithium carbonate when she was admitted to hospital following a myocardial infarction. At this time asymptomatic hypercalcaemia was discovered. Lithium carbonate was discontinued, as it may induce hyperparathyroidism.

Thereafter the patient experienced three further manic-depressive mood swings, and as a consequence lithium prophylaxis was reinstated. Assessment of renal function revealed a creatinine clearance of 35 ml/min, indicating an impaired glomerular filtration rate. Frusemide 40 mg *alt. die* was required to control congestive cardiac failure. The combination of a natriuretic diuretic and the compromised glomerular filtration rate may explain the low dose of lithium carbonate (200–250 mg per day) required to maintain serum lithium levels within the normal therapeutic range. The patient, despite the combined risk, was safely maintained at stable serum lithium levels without any untoward effects.

Six months after recommencing lithium carbonate, however, she presented acutely with symptoms indicative of lithium toxicity: ataxia, mild dysarthria, disorientation, and decreased attention span. Clinical assessment and investigation revealed no other abnormalities. The only recent change in medication was the introduction four days previously of mefenamic acid in a dose of 250–500 mg *q.i.d.* for the relief of pain arising from cervical osteoarthritis. The patient reported that she had previously taken mefenamic acid without side-effects during the time when lithium prophylaxis had been discontinued. A serum lithium estimation 6–8 h after the onset of lithium toxicity was 1.16 mmol/litre, which is close to the upper limit of normal. Although symptoms of lithium toxicity can occur within the normal therapeutic range, especially in the elderly, it seems probable that the serum lithium level would have exceeded the upper limit of normal (1.5 mmol/litre) if venipuncture had been closer to the time of lithium ingestion, approximately 10 h previously.

Discussion

The role of prostaglandins in the maintenance of normal renal function is uncertain (Gullner *et al*, 1980). However, their role is more clearly established in cases where renal function is already compromised, such as with renal disease or cardiac failure (Sellars & Wilkinson, 1983). In such cases, inhibition of prostaglandin synthesis or receptors is likely to compromise renal function further, thereby reducing renal elimination of drugs like lithium. Furthermore, NSAIDs are recognised to have adverse effects on the kidney (Calin, 1983). Predisposing factors to NSAID induction of renal failure include age and diuretic therapy (Henrich, 1983); in particular, NSAIDs may antagonise the effects of frusemide (Yeung Laiwam & Mactier, 1981).

The facts that the patient had previously taken mefenamic acid without any problems and that, whereas she had been safely stabilised on lithium for some time, the onset of toxicity only occurred shortly after commencement of mefenamic acid suggest that this was an interaction between lithium and the NSAID. This is supported indirectly by reports of similar effects with other NSAIDs. Rechallenge, however, was thought unjustifiable because of the potential hazards to the patient; thus the possibility that toxicity was unrelated to mefenamic acid has not been completely excluded.

The question arises as to the mechanism involved. In this case the patient was probably vulnerable to the development of lithium toxicity by virtue of age, impaired glomerular filtration rate, and associated natriuretic diuretic therapy. Because of her physical condition, the prostaglandin system was likely to have been important in maintaining optimal renal function. When a prostaglandin inhibitor, mefenamic acid, was introduced, it probably acted as the trigger for the development of raised serum lithium levels through the further impairment of renal lithium excretion.

This possible interaction suggests that precautions, such as more frequent serum lithium estimations and a reduction in lithium dosage, should be taken whenever lithium and mefenamic acid are combined, especially in those patients where prostaglandin inhibition is likely to have important clinical consequences.

The Effect of Maternal Psychotic Illness on a Child

We report the case of an 11-year-old girl who had been living with only her mother, a woman with chronic schizophrenia. The girl had been caught shoplifting with her mother, and had a long history of non-attendance at school. The case emphasises that adult psychiatrists should always consider the impact of chronic parental psychiatric disorder on children, particularly in one-parent families.

This case was of interest to one of the authors (AJM) as he had been involved in the mother's presentation during her first, and so far only, admission to a psychiatric hospital.

Case report

An 11-year-old girl, G, the only child in a single-parent family, came to our attention with a four-year history of increasing non-attendance at school. Three years previously, her mother, then aged 38, was admitted to a psychiatric hospital with a diagnosis of chronic schizophrenia. During that admission, the mother described many psychotic symptoms which she had experienced intermittently for about eight years. These included auditory and visual hallucinations, a well-developed grandiose delusional system, and ideas of reference. For instance, she described the emission of a great heat and light coming from a cross on her bedroom wall, that had frightened her so much that she had to take it down. She had seen pictures of a man with a beard and wreaths around his head on the wall and thought this was Jesus Christ. She also had heard evil voices from her stomach calling her names and she was convinced these were from a "higher medium". She thought she was an important person in "The Movement", with special powers. She insisted she was trying to resist being taken to "the astral plains to see God". She talked in a vague and mysterious way about being "tuned in to Ronald Reagan and Margaret Thatcher", but could not describe this connection more clearly. She hinted that things were going on that were too dangerous to talk about, but she was convinced that the interviewer knew about these happenings. She described pains in her foot "like a nail being put through it", without any supporting evidence. She experienced "sex vibrations" inside herself that she interpreted as a sign that Jesus Christ was making love to her. Finally, she was convinced that people were plotting against her and wanted to harm her.

Treatment with phenothiazines reduced her agitation, without affecting her delusional system. The possible impact of the mother's chronic illness on G was not recognised by the hospital psychiatrists, even though the mother had said that "these things must be happening because G experiences them too". The latter statement was regarded as part of the mother's continuing psychotic illness rather than as evidence of the daughter's involvement. G was not interviewed at this time, nor was the family seen at home. Two weeks after admission, the mother took her own discharge and was soon lost to follow-up investigation.

During the next three years, there was further evidence of the detrimental effect of the mother's illness upon G: G was caught shoplifting with her mother; school attendance was irregular and erratic; referral was necessary to the Children's Panel (the equivalent in Scotland of the juvenile court system in England and Wales). G was received into care and placed with foster-parents. The panel subsequently requested a psychiatric opinion, prompted by a strange quality in the mother and daughter's relationship, as well as the mother's lack of concern about G's schooling. Neither the school, the education department, the social work department, nor the Children's Panel were aware of the mother's chronic mental illness, this possibly explaining the delay in referral to child psychiatry.

At the initial joint interview, the mutually dependent and inappropriately close relationship between mother and child became very apparent. They had slept together, and spent most of the day together, as the mother did not work and G had not attended school on any regular basis for some time. G was very protective towards her mother, interrupting when her mother began to talk about her strange experiences, effectively preventing her mother from saying too much. G also said that she was so concerned about her mother that she was reluctant to leave her mother alone in the house.

The mother described psychotic phenomena similar to those described previously, adding that her daughter had similar experiences. G agreed, saying that she heard voices uttering obscenities and swearing and that she had seen a crucifix on the wall: G was reluctant to elaborate further, simply saying "the same as my mum". G did not seem concerned about these events, which only occurred when she was with her mother, implying that G was agreeing with her mother in order to avoid upsetting her. Consequently, we did not think she was independently psychotic.

When interviewed alone, G was a pleasant, co-operative girl, with good rapport. There was no evidence of any hallucinations or delusional experiences. She was, however, unwilling to discuss the unusual experiences described by her mother, saying that they were in the past and were best forgotten.

Independent information provided by the foster-parents confirmed that G had not shown any bizarre behaviour or reported any unusual experiences. Additional information from the school revealed that her IQ was 85, and her reading age 7 years 9 months, at a chronological age of 11 years 5 months. The school were especially worried about G's emotional immaturity, describing her as "childlike", with poor peer relationships. Her teachers thought that she would be at great risk at an ordinary secondary school, particularly because she was physically mature and superficially appeared older than her years.

The subsequent psychiatric report to the Children's Panel recommended residential school placement for G, with regular liaison between home and the school from the social work department. G has now been away at school for two terms and is progressing well.

Discussion

The association between parental mental illness and disturbance in children has been recognised for over half a century. Rutter (1966) showed that the parent–child association of psychiatric disorder was strongest when the parental symptoms impinged upon or were involved with the child in some way. The children were most at risk when they were the victims of aggressive acts of hostile behaviour, were the target of parental delusions, were neglected for pathological reasons or were involved in parental symptoms. Other studies of clinical and general population samples have confirmed this association, with the greatest risk when the illness is chronic or recurrent (Beardslee, 1986; Cytryn *et al*, 1986; Quinton & Rutter, 1984; Weissman *et al*, 1984).

In this case, the mother's chronic psychotic illness was responsible for the development of an over-close and over-dependent relationship with her daughter, with serious detrimental effects on the child's education, independence, and peer relationships. Although the child's bizarre statements were not psychotic, the case shows how a child may become so involved in the parental psychopathology that she complies with parental requests for confirmation of psychotic experiences and also refuses to attend school in order to protect and look after her psychiatrically disturbed parent.

Many of G's problems might have been averted if she had been seen during her mother's admission, when the adverse effects of the mother's illness on G would have been apparent. Adult psychiatrists should always consider the whole family, especially in one-parent families, when a parent has a major psychiatric illness. The consequences of this omission in G's case was a further three years of poor school attendance, with impaired social development. A family assessment could also have alerted the social work department and the Children's Panel to the child's needs at an earlier stage. Finally, we would recommend strenuous efforts to maintain follow-up investigations with such cases, with the involvement of the community psychiatric nursing services and the general practitioner, to ensure that the risks for children in such situations are anticipated and, one hopes, ameliorated.

Early-onset Huntington's Chorea

Diagnostic Clues

A patient with early-onset Huntington's chorea is described. The diagnosis had been overlooked during previous contacts with psychiatric services because there was no family history, and features typical of the adult disease were absent. Distinctive findings on CT scan and electroencephalography were observed.

The early onset of Huntington's chorea can lead to marked diagnostic difficulty, particularly in the absence of a positive family history. The so-called 'juvenile' variant is characterised less often by chorea than by extrapyramidal rigidity, dysarthria, and occasionally, cerebellar signs. Intellectual deterioration with failure at school and difficulty with concentration are usually the presenting features, but may for some considerable time be attributed to poor initial endowment. Personality change, accompanied by anxiety, is often prominent. Though depression is held to be the most common affective disturbance in Huntington's chorea, its true incidence is difficult to determine. The incidence of schizophreniform psychosis preceding or accompanying the abnormal movements varies from 5% (Brothers, 1964) to 12% (Oliver, 1970), and the delusions are usually paranoid in nature. There is no obvious relationship between this presentation and other clinical features (such as chorea or dementia), but it seems that schizophreniform psychosis is more commonly seen in younger patients with Huntington's chorea and that it may be an associated feature of the disease (Garron, 1973). Seizures occur in up to a half of patients affected in childhood, in contrast to their rarity in the adult disease.

The prevalence of early-onset cases among patients with Huntington's chorea has been variously estimated at 1% (Stevens, 1976) and at 10% (Oliver, 1970). Hayden & Beighton (1982) found that 4.7% of 2699 cases in the literature had begun before the age of 20. This may yet represent an underestimate. Progress of the disease was noted by Hayden (1981) to be more rapid than in adults. An intriguing feature is the finding that children with Huntington's chorea have an affected father approximately four times as frequently as an affected mother (Osborn *et al*, 1982), though the possibility of sampling errors in contributing to this cannot be excluded (Vegter-Van Der Vlis *et al*, 1976).

We report here a young man who presented to a hospital for the mentally handicapped after a history of various social and psychiatric problems from about the age of 11. The diagnosis of Huntington's chorea was made only at the age of 27, and shortly thereafter he died. Important clues to the diagnosis lay with distinctive findings on the CT scan and the electroencephalogram. He was illegitimate and the fate of his father was unknown. There was no positive family history.

Case report

In 1983 a single 25-year-old man was admitted to a hospital for the mentally handicapped. He was judged at that time to have low intellect and to suffer from a personality disorder and depression. Physical signs on admission included ataxia, tremor, muscular rigidity, and dysarthria, but neurological opinion was that these were attributable to the neuroleptics he had been given. There was no family history of psychiatric disorder.

Labour had been prolonged, but otherwise birth and early development were normal. His mother described him as a bright and inquisitive child who had performed well at primary school. At the age of 11, a verbal reasoning test had shown an IQ equivalent of 103.

From then on, however, he showed decreased willingness to work, vagueness, and increasing indiscipline. Over the years he became physically aggressive, with truanting, stealing and 'failure to mature'. He was noted to be generally anxious. Upon leaving school he obtained numerous labouring jobs, felt to be inconsistent with his early educational promise. The first of many appearances for theft at juvenile courts took place at the age of 16.

At 18 he was assessed psychiatrically as having a personality disorder with depression. At 20 his IQ was measured at 86, with a mental age of 13 years 4 months. At about this time his speech became difficult to understand because of slurring, and he became progressively more withdrawn. During several hospital admissions thereafter, he was variously regarded as psychotic and mentally handicapped, and was treated with a variety of neuroleptics, without clear evidence of benefit. At 22 he was deemed fit to plead to charges of indecent exposure and of a sexual offence against a pet dog.

In hospital from 1983 onwards he remained withdrawn, anxious, and extremely slow both verbally and physically. He ate poorly, complained of abdominal pains, and lost a great deal of weight. Psychometric assessment was very difficult, but in 1984 he scored an IQ equivalent of 67 on the coloured progressive matrices and obtained a level of only 4 years 7 months on the Vineland Social Maturity Scale. All medication was discontinued in 1984.

On detailed review in 1985 he showed marked slowness and anergia and walked with a stooped, wide-based ataxic gait. He replied monosyllabically to questions, with a marked dysarthria, but proved to be oriented and to know his age. Reading and writing skills appeared to be intact. Tone was markedly increased in the arms but not in the legs, and all tendon reflexes were exaggerated. The plantar responses were probably flexor. The fingers of the left hand showed abrupt jerking movements, mainly when handled but occasionally spontaneously, and there were jerking tremors around the mouth. He found difficulty in rising from the seated position, although there was no evidence of muscular wasting. The cranial nerves and optic fundi were normal. Sensory examination was difficult to perform, but revealed no clear deficits. The extremities were markedly blue and cold.

The diagnosis was felt to lie between Huntington's chorea and Wilson's disease or some more obscure neurological degenerative condition. An EEG revealed a very low-amplitude tracing, almost totally devoid of alpha rhythm, with bursts of low-amplitude theta waves bilaterally from time to time. A CT scan was also abnormal, with moderate diffuse atrophy and flattening and concavity of the lateral borders of the anterior horns of the lateral ventricles due to shrinkage of the heads of the caudate nuclei (Fig. 1(a)). Review of a CT scan carried out 18 months earlier, and then considered to be normal apart from some prominence of sulci, showed, with hindsight, similar features. An EEG carried out in 1984 had also been reported as abnormally flat and featureless. On the basis of these investigations a diagnosis of Huntington's chorea was made.

Over the next few weeks the patient declined abruptly, with a marked increase in extrapyramidal rigidity, then died suddenly, with post-mortem evidence of pneumonia. Examination of the brain confirmed Huntington's chorea. The brain was smaller than normal, weighing 1131 g, with mildly widened sulci. The caudate nuclei and putamina were small. The medial borders of the heads of the caudate nuclei were straight, not convex, with corresponding enlargement of the frontal horns of the lateral ventricles (Fig. 1(b)). These appearances corresponded to what was seen on the CT scans. Microscopy showed a loss of nerve cells – particularly the small nerve cells – in the striatum, with a

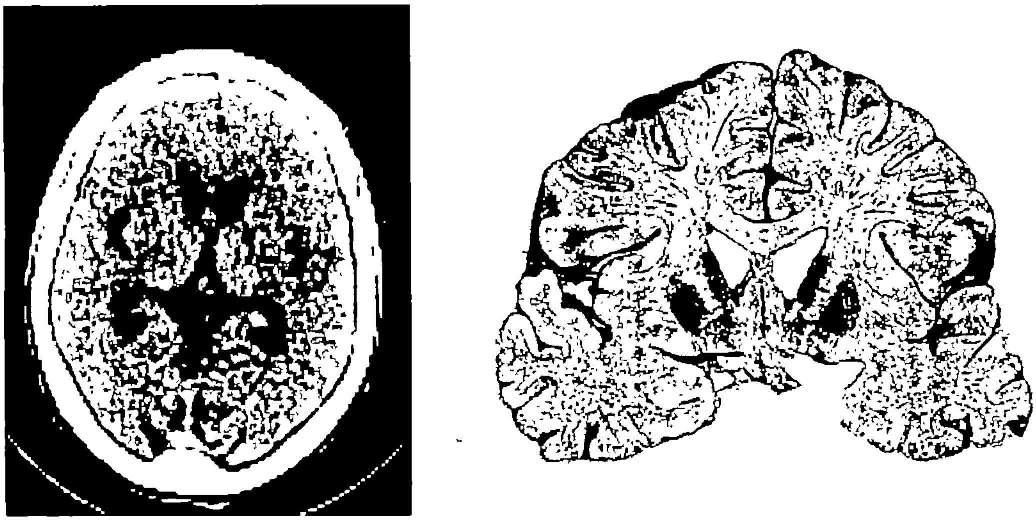

FIG. 1 (a) CT scan; (b) autopsy appearances, illustrating shrinkage of heads of caudate nuclei.

prominence of astrocytes. Some of the bundles of axons, the so-called pencils of Wilson, in the affected striatum, were pale in sections stained for myelin and for axons, rich in small dark nuclei and astrocyte processes. There were no other obvious microscopic abnormalities in the cerebral hemispheres or in the cerebellum and brain stem.

Discussion

The patient we report highlights the difficulty in the diagnosis of Huntington's chorea when a family history is not forthcoming and when the typical choreiform movements are absent. The 15-year-long presentation, with decline in performance from schooldays onwards, antisocial conduct, and quasi-psychotic developments, obscured the true situation, and the administration of neuroleptics led to misinterpretation of the significance of the extrapyramidal features he displayed. The frequency of this form of motor abnormality in juvenile-onset Huntington's chorea is still probably insufficiently appreciated.

The importance of distinguishing dementia from amentia is similarly illustrated here. The prominence of behavioural disturbance, and the patient's disorganised social background, led to an undervaluing of the history of his early progress at school. A label of mental handicap was too readily applied, and no doubt delayed the search for responsible brain pathology.

The value of the often distinctive features on the electroencephalogram and CT scan in pointing towards Huntington's chorea deserves close attention, and would appear to warrant wider application in patients who show intellectual and/or social deterioration of obscure cause.

Two Cases of Erotomania (de Clérambault's Syndrome) in Bipolar Affective Disorder

Two female patients with longstanding bipolar affective disorder demonstrated de Clérambault's paradigm of erotomania during the euthymic phase of their illness. Although a diagnosis of schizophrenia or paranoid disorder is often given, a review of the literature shows that many cases have features of a major affective disorder, probably bipolar affective disorder and its spectrum.

The belief that love could be a form of, or the cause of, madness has a long history and many entities have fallen under the rubric of erotomania. De Clérambault advanced the concept of pure erotomania, one of the "*psychoses passionnelles*", as a distinct disorder in the 1920s. The "fundamental postulate" required the sudden, precise onset of a woman having "the conviction of being in amorous communication with a person of much higher rank, who has been the first to fall in love and was the first to make advances" (Enoch & Trethowan, 1979); the delusion persists chronically, with the elaboration of secondary themes.

Controversy still centres on the place of this condition in psychiatric nosology, due in part to the poor descriptions of premorbid history, personality, and phenomenology. The DSM-III restricts the delusions of the paranoid disorders to persecution and jealousy, making it difficult to assign a place to erotomania.

Erotic delusions, including a wide range of sexually related beliefs (sexual pursuit by an enamoured party, jealousy, impending marriage, pregnancy, rape, and venereal disease), are common, occurring in one third of women with psychosis (Rudden *et al*, 1978).

Ellis & Mellsop (1985) discussed the content of 58 cases of de Clérambault's syndrome with regard to conformity to the presence of the fundamental postulate and its derivatives, finding it variable. They concluded that the syndrome did not merit a separate nosologic category, and that most cases could be classified as having schizophrenia or related disorders. However, a mental disorder cannot be characterised by its content or cross-sectional picture alone, and attention must be paid to its form, the disturbance of mood, course, outcome, and response to treatment.

We present two cases of erotomania in women with bipolar affective disorder arising or persisting during periods of euthymia.

Case histories

Case 1

Ms A is a 48-year-old right-handed single female whose father was alcoholic. Of her three siblings, one brother is alcoholic, with paranoid traits; a female first cousin has bipolar affective disorder.

Although her family was not particularly devout, the patient joined a Carmelite convent at age 17, which she was forced to leave two years later because of bizarre behaviour and sexual preoccupations.

First psychiatric contact was for depression upon leaving the order. The patient worked, mostly as a private-duty nurse, until 1979, when she went on disability pension. Her first admission to hospital occurred at age 26, with the diagnosis of schizophrenia, and she had six subsequent admissions, all of which averaged 3–4 months and were treated with neuroleptics. However, the patient showed clear episodes of mania and depression interspersed with periods of euthymia.

The first admission was precipitated by an erotic delusion concerning a physician. Similar delusions involved an orthodontist for seven years and a doctor in sociology over ten years. For the past seven years her delusions involved a hospital staff member. She sent letters, gifts, and pictures to him, while attributing letters soliciting intercourse to him; the ward staff were seen as trying to thwart the expression of their love for each other. These beliefs were maintained during periods of euthymia, although they intensified considerably and led to action during hypomania. .

The mainstay of treatment had been neuroleptics until 1976, when lithium carbonate was started, although chlorpromazine 50–100 mg was used for sedation. The affective episodes were partially controlled by lithium but she was only infrequently compliant; serum level never exceeded 0.75 mmol/litre.

A trial of carbamazepine 200 mg t.i.d. achieved a serum level of 25 μmol/litre (therapeutic range 17–50 μmol/litre). When it was increased by 200 mg, the patient's affective state normalised and she renounced her delusions completely. However, she grew less adherent to the treatment regime and further blood levels could not be obtained, with an admission to hospital ensuing soon thereafter.

Case 2

Ms B is a 64-year-old single woman who has had a number of admissions due to depression and elation. Her first psychiatric illness was at 26 when she had a mild, quickly remitting depressive episode. After a suicide attempt at age 45, she was admitted to hospital and treated with ECT, with a relapse the following year. At age 59 she had a one-week episode of hypomania and thought that she was the reincarnation of Christ. Following this episode she was maintained on small amounts of perphenazine, which she has refused to reduce despite lack of psychotic symptoms.

During her latest admission, she had a severe retarded suicidal depression. Clomipramine produced a rapid switch in mood, with elation and racing thoughts. She agreed to a trial of ECT, which with perphenazine left her less depressed but still delusional, with some fluctuation between states. She achieved a euthymic state with no evidence of delusions on the combination of lithium and perphenazine, re-establishing her social and work life quickly.

Six months later and the day after her regular appointment, she called her psychiatrist to say that she was disappointed because she had waited at home expecting his visit. She knew her feelings of love were reciprocated but appreciated that he could not openly profess his feelings because of the professional relationship. The delivery of many letters and cards expressing her affection soon followed. Ms B interpreted his continued refusal to visit as proof of his love for her and thought she could determine his thoughts. She has continued to send letters at regular intervals and to allude to their relationship.

She has been very compliant with her medication and has remained euthymic, with no evidence of delusional thought in other areas of her life. She had no previous episodes of delusional erotomania.

Discussion

Several psychological explanations for erotomania have been proposed. Self-love, denied or projected on to another person, or as a displacement from unconscious homoerotic trends similar to those in pathological jealousy; struggles with unsatisfied affection; and the wish for rebellion against social roles have been proposed as causative. The syndrome has also been viewed as serving an adaptive function, providing an externalised source of nurturance, protection, and control during periods of strain to mask depression and loneliness (Enoch & Trethowan, 1979).

Hollender & Callahan (1975) divided erotic delusions into two subtypes: a primary or pure form, with sudden onset, fixing upon a single object and developing into a chronic encapsulated system (paranoia); and a secondary one, with gradual onset, superimposed on other previous symptoms (schizophrenia). Although there is little formal consideration, the literature supports a predominant role for severe affective disorder rather than schizophrenia or paranoid disorder in producing this delusional symptom; only Guirguis (1981) and Remington & Book (1984) clearly report their cases as having bipolar affective disorders. Hypersexual behaviour or promiscuity is not uncommon. Erotic delusions, appearing prior to the index episode or as recurrences, are frequent, as well as waxing and waning of the presenting delusion.

In terms of disturbances which may be included under affective disorders, recognised and often unrecognised bipolar affective disorder, "grandiosity", secondary mania, borderline personality disorder, "hysterical psychosis", and numerous cases of depression can be found.

A more precise recording of phenomenology may permit valuable clinical distinctions to be made. After separating changes in libido, particularly hypersexuality often found with hypomania and mania, several categories of erotic delusions (erotomania) can be described. These are:

(a) persecution (e.g., erotic pursuit, influence, and control)
(b) ideas concerning the conduct of oneself and/or others (e.g., jealousy, homosexual reference)
(c) delusional relationship (e.g., de Clérambault's, "incubus", "phantom lover")
(d) somatic delusions (e.g., rape, pregnancy, venereal disease, metamorphosis).

Erotomania has been believed to be relatively resistant to psychotherapy and to pharmacotherapy, with chronicity the rule (Enoch & Trethowan, 1979). However, a review of the few reports that record treatments does not bear out this gloomy opinion. Cocchi *et al* (1982) reported the "anti-erotic" effect of chlordesmethyldiazepam, a GABA-ergic agent, on five patients, of whom one was depressed and three (including Case 4) probably had bipolar disorder. Responses to lithium (Remington & Book, 1984), ECT, and antidepressants and neuroleptics (Guirguis, 1981), as well as previous response to ECT, provide further evidence in favour of a role for severe affective disorder.

Conclusion

Erotic delusions are common in a number of forms of affective disorder, particularly in the bipolar spectrum. As well, patients with paranoia, especially those with grandiosity or affective features, may present with erotomania; these may represent mixed states, unrecognised affective disorder, or mood-congruent delusions which persist into the euthymic state. The mood changes, or waxing and waning of the intensity of the beliefs may be falsely ascribed to the vicissitudes of the content of the delusion, psychodynamic changes, or psychosocial stressors.

Only with appropriate trials of medication, considering the possible origins of these delusions in affective disorder, can the importance of this category of delusional content be understood.

A Case of Self-Inflicted Leucotomy

A suicide attempt with a gun resulted in left frontal lobe damage in a 19-year-old obsessive man. While intelligence did not suffer and no frontal lobe syndrome emerged, the patient's obsessive rituals were significantly reduced.

The advance of medicine is frequently furthered by natural experiments, as this report of unintended psychosurgery, in a patient with severe obsessive compulsive disorder (OCD), vividly illustrates.

Case report

On 11 November 1983, Tom, 19 years old, was found with blood running down his face. He had shot himself through the mouth with a .22 calibre rifle. Shortly thereafter, he was admitted to neurosurgery.

A CT scan revealed blood in both maxillary sinuses. The bullet had penetrated through the ethmoid sinus and the cribriform plate, and penetrated to the base of the left frontal lobe. The bullet was lodged in the premotor cortex, and fragments could be seen along the left-side pathway through the head of the caudate nucleus and splenum of the corpus callosum. The patient manifested a mild right-sided hemiplegia, involving the leg more than the arm.

The onset of his OCD followed shortly after he became aware of his homosexuality at age 10 (father accepted it but mother was very upset). Obsessive ideas of contamination, and minor checking and hand-washing rituals did not interfere with his life, including his studies, until age 15. He was then admitted to hospital for OCD, and treated with a combination of exposure and response prevention and supportive psychotherapy, but without benefit. At age 16 he first presented to one of the authors (LS), suffering from compulsive doubt, checking, hand-washing, and shower-taking. He was also depressed, feeling hopeless, lacking interest and pleasure in almost everything, feeling weak and tired, oversleeping, and blaming himself for not being able to continue his studies or go to work. Formerly an 'A' student, his grades had deteriorated and he had left school. When psycho-, behaviour, and pharmacotherapy (clomipramine to 200 mg daily) effected no change in OCD or mood, he left treatment.

During the next two years he made two suicide attempts, thinking that if he sacrificed his life, he would expiate God, his father would drink less, and his mother would be more loving and kind. He then returned to treatment. His depression was more severe, and in addition to the earlier OCD symptoms, he had to repeat ideas in order to gain perfection, and had to recall 50 different chants.

He was placed on phenelzine 15 mg t.i.d. Three weeks later, he became frightened at his inability to ejaculate. His mother threatened him with commital to a mental institution, and when he complained to her about how wretched he felt, she replied: "Go and shoot yourself." Five minutes later he did so.

Three weeks after neurosurgery, he underwent neuropsychological testing and an initial assessment of OCD. The same obsessions as before the suicide attempt were present, but at a much lower frequency and intensity. His bathroom rituals had decreased from four hours pre-injury to half an hour.

During the next two months he remained in hospital on the psychiatric ward, where he received behaviour (exposure and response prevention) and drug therapy (phenelzine to 75 mg daily). His compulsive hand-washing, toilet ritual and checking were gradually reduced to a daily average of 15 minutes. Because he remained depressed, he was placed on carbamazepine 400 mg b.i.d. After two weeks, he rated himself as "mostly cheerful". He was discharged, and followed up at monthly intervals. He continued on carbamazepine for one year but did not receive further behaviour therapy.

At two years post-discharge, his mood remained consistently calm and cheerful. He completed his high school education. His obsessions were minimal – he remained intolerant of disorder and demanded that the kitchen and bathroom be kept spotless.

Neurological examination was normal except for anosmia. A CT scan revealed that part of the left frontal lobe was infarcted. There was no sign of social disinhibition, tactlessness, or lack of drive – no indication of frontal-lobe syndrome.

On neuropsychological measures, he showed impairment of right-handed fine motor co-ordination, and right-hand performance in the Finger Tapping test (Reitan & Davison, 1974); impairment was shown also on the Controlled Oral Word Association Test (Benton, 1968), which is particularly sensitive to left frontal damage (Crockett *et al*, 1986). Performance on the Wisconsin Card Sorting Test was unimpaired. Patients with right frontal lobe lesions make more errors on this task (Drewe, 1974).

There was marked improvement in intellectual functioning. Scores for IQ on the Wechsler Adult Intelligence Scale before (1980) and after (February 1984) the suicide attempt and at two-year follow-up (February 1986) were

verbal: 115, 110, 121
performance: 117, 120, 140
full scale: 116, 114, 133.

There was also marked improvement on psychometric tests of obsessions (self-rating), fears and phobias (Fear Survey Schedule), anxiety (Institute for Personality and Ability Testing Anxiety Scale), and introversion and neuroticism (Maudsley Personality Inventory). At the three testing points (before, after and follow-up) his Leyton Obsessive Inventory scores were

symptom: 32, 21, 12 ($P<0.01$)
resistance: 38, 32, 13 ($P<0.05$)
interference: 51, 24, 11 ($P<0.01$)

and Beck Depression Inventory scores were -32, 6 and 5 ($P<0.05$).

Discussion

It seems likely that the observed changes were not just coincidental to the self-inflicted psychosurgery. The rate of spontaneous remission or, at least, improvement in OCD patients is estimated at 40% (Rachman & Hodgson, 1980) to 70% (Pollitt, 1957). The most favourable estimates include cases of recent onset (e.g. three-month duration for adult onset), and show a slower time course. Black (1974), however, summarising four major reports, found a static course in 54–61%, and progressive worsening in 33%. In the case described here, early onset and a chronic, progressively worsening course, the dramatic and almost immediate effects of unilateral leucotomy, and the sustained improvement over two years rule out spontaneous remission.

There is a striking similarity between the anatomic and psychological changes of our patient and those reported after psychosurgery of the fronto-orbital cortex and anterior cingulum. Kelly (1973) cites dramatic changes in mixed depressive and obsessional states, the depressive symptoms being relieved by the frontal lesion, and the obsessive symptoms by the cingulectomy, with intelligence, learning, drive level, and control unaffected.

The neuropsychological and power spectral findings of Flor-Henry *et al* (1979) suggest predominantly left frontal function in OCD, and this is consistent in the present case with the site of the lesion.

The issue of concomitant factors should be raised. Several factors may have influenced the OCD in addition to the anatomical change. The drama of the suicide attempt, with its attendant notion of 'hitting bottom'; the subsequent stay in hospital, necessitating removal from a noxious home environment; perhaps the mother's changed behaviour, being somewhat more regretful than earlier, may all have been instrumental in bringing about the observed improvement. However, previous suicide attempts, periods in hospital, and removal from the home had not improved his condition. In a fashion similar to that achieved by psychosurgery, the self-inflicted left frontal damage altered the course of OCD. Hence we conclude that in this case of self-inflicted neurosurgery, the change in brain anatomy led to the psychological change – a change that seems to be permanent.

Rudolph Hess's Mental Illness

SIR: The recent suicide of Rudolph Hess, aged 91, in Spandau Prison recalls the spirited controversy about his correct psychiatric diagnosis (Dicks *et al*, 1947; Slater, 1972). When Hess parachuted into Scotland on 10 May, 1941, he was Deputy Führer and a close friend of Hitler. Hess claimed he made the jump in order to make contact with the Duke of Hamilton, who would take him to King George; together they would arrange to stop the war. The immediate impetus for Hess's flight to Scotland, according to his own account, was a dream by a friend whom he believed was a prophet. German radio attributed Hess's flight to "an illness of many years' standing. . .mental derangement" and added that "the National Socialist Party regrets that this idealist fell a victim to his hallucinations."

Almost immediately Hess was noted by his captors to be depressed and to be expressing beliefs about a plot to poison him. Within one month of his landing he was examined by psychiatrists – Brigadier-General J. R. Rees and H. V. Dicks. The latter spoke fluent German. Rees diagnosed Hess as suffering from "a psychopathic personality of the schizophrenic type", while Dicks' immediate impression was "typical schizophrenic"; Dicks later diagnosed "paranoid psychosis". In subsequent months Hess was noted to have auditory hallucinations, much evidence of delusional thinking, and odd behaviour "such as lying with his fingers in his ears smiling to himself". He also made two suicide attempts, fracturing a femur in a leap shortly after his arrival in 1941 and stabbing himself in the chest in 1945. Hess's clinical picture was complicated, however, by intermittent amnesia "which varied with circumstances and with the observer, and at times suggested malingering rather than hysteria".

On 10 October, 1945, Hess was taken to Nuremberg to stand trial for war crimes; the question was whether he was mentally competent to stand trial. A Rorschach protocol indicated "the possibility of a psychotic episode". However, initial psychiatric examination by Major Kelley concluded that Hess had "a severe psychoneurosis of the hysterical type". Hess was therefore examined by American, British, Russian, and French physicians. The Americans (D. Ewan Cameron, Nolan D. C. Lewis, and Paul L. Schroeder) concluded that Hess "is suffering from hysteria characterised in part by loss of memory" and "is not insane at the present time in the strict sense of the word". The British (Lord Moran, J. P. Rees, and George Riddoch) diagnosed Hess as "a psychopathic personality" with "a marked hysterical tendency" and declared that "He is not insane in the strict sense". The Russians (Professors Krasnushkin, Sepp, and Kurshakov) labeled Hess's illness "a psychogenic paranoid reaction" with "hysterical amnesia", and said "there are no changes typical of the progressive schizophrenic diseases". The French (Professor Jean Delay) participated in both the American and Russian examinations and tried to conduct a narcoanalysis of Hess, but he refused. Hess was allowed to stand trial, was found quilty and was sentenced to life imprisonment.

Slater (1972) published a little-known but sharply-worded critique of the psychiatric conclusions, and especially of the part played by J. P. Rees. Slater claimed that, "the conclusion is irresistible that Rudolph Hess had a schizophrenic psychosis. . . The psychotic process came in a series of acute attacks. . . It is very difficult to explain the incapacity or unwillingness on the part of the psychiatrist [*sic*] to reach this diagnosis." Slater continued, "If the diagnosis of schizophrenia is correct, then there would seem to have been serious deficiencies in the clinical judgment or the open-mindedness of a number of distinguished world psychiatrists . . .The diagnostic blindness, the failure to reach an obvious conclusion becomes a problem in its own right, demanding explanation."

Rees, according to Slater, was the key to the error. Rees's understanding of "psychopathological phenomena on exclusively psychodynamic lines" and his contention "that diagnosis is a bagatelle" led to "the results of grave misconceptions of the task of the psychiatrists of what constitutes psychiatric knowledge, and of the function of psychiatry as a medical discipline *vis-à-vis* the individual patient". Rees, as the only psychiatrist on the British examining team and as the only person present with extensive involvement with the case, was in a position to influence the others. This, in Slater's opinion, "led to a trial which seems now to have been a miscarriage of justice".

In his 1972 article Slater called for the release of the subsequent psychiatric records on Hess when he died, to settle the diagnostic issues. From 1946 until his recent death, over 41 years of such records have accumulated. What effect, for example, did Hess's psychiatric status have on the decision not to release him from Spandau? If Hess was psychotic, was he treated during those 41 years? What effect did press reports that Hess might be malingering have on the decision to try him at Nuremberg? Since Hess was a Deputy Führer whose flight to the West was deeply embarrassing to Hitler, did political considerations enter into the diagnostic decision to not label him as insane? If Hess was psychotic, what was his mental status as Deputy Führer when he and Hitler were formulating the policies which led to the war? It is also interesting to contrast the case of Hess, apparently psychotic but found fit to stand trial, with the simultaneous case in the United States of Ezra Pound, who was not psychotic but claimed to be unfit to stand trial on 19 counts of treason (Torrey, 1983).

In the interest of history, the psychiatric records of Rudolph Hess should be made available for professional examination.

Expressed Emotion and First Episodes of Schizophrenia

Sir: The debate about the validity of the Northwick Park Study in the papers by Mintz *et al* and Macmillan *et al* (*Journal*, September 1987, **151**, 314–323) highlights a number of important issues about the EE concept. The level of discrimination between high and low EE in predicting relapse among first-episode schizophrenics, whether significant or not, is certainly lower than in previous studies of EE in undifferentiated samples. In fact, Leff & Brown (*Journal*, April 1977, **130**, 417) have previously revealed that the nine-month relapse rates for high EE first admissions is 38% (compared with 13% for low EE) and 69% (compared with 17%) for readmissions. If high/low EE are stable characteristics, why should such temporal changes in predictive power be observed? The possibility that EE may in fact be an unstable characteristic is revealed in the recent large-scale study of Hogarty *et al* (1986): 25% of the high EE sample not exposed to family treatment 'spontaneously' reduced to low EE, compared with 39% who reduced under family treatment. In both groups no relapse was observed, suggesting perhaps that the spontaneous reduction in high EE was genuine and not an artefact of measurement. It seems that there is an important developmental dimension in the genesis of stable EE which is concerned with the cumulative interaction of inherent schizophrenic vulnerabilities and the family system (Birchwood & Smith, 1987).

Macmillan *et al* discuss the applicability of EE: only one-third of their sample come from a family home, and of these only a minority were high EE. Our experience is roughly similar, although we have observed that many first admissions return to the family home subsequently; McCreadie & Robinson (*Journal*, May 1987, **150**, 640–644) found that 50% of their undifferentiated sample lived with a relative. It is not at all clear to us that low EE families cope in a 'model' way; in some cases we have observed that families manage the burden of living with schizophrenia in such a way as to exacerbate other clinical or social features, such as social withdrawal (Birchwood & Smith, 1987). The prelevance of high EE does not therefore adequately reflect the therapeutic or service implications of family interventions.

Finally, Macmillan *et al* draw attention to the comments of Hogarty *et al* (1986) that family interventions delay rather than prevent relapse and that the success of these interventions might be inflated by drug defaulters among the controls. It is important to recall that many have argued that neuroleptics themselves serve to delay relapse (Englehart *et al*, 1967) and that, to quote Macmillan *et al* (*Journal*, February 1986, **148**, 128–133), "relapse rates were lower on... medication than placebo, *but however assessed, outcome at this early stage was poor for many patients*" (our italics).

Clearly, we have no cause for complacency, and both environmental and biological research needs to be actively encouraged and pursued.

A Comparative Trial of Amitriptyline and Fluoxetine

Sir: The comparative trial of amitriptyline and fluoxetine in depressed out-patients by Young *et al* (*Journal*, September 1987, **151**, 337–340) found no significant difference in outcome except for a slight difference, discounted by the authors, on the Beck Scale for Depression (BSD). Improvement in BSD scores commenced in the first week, and six-week improvement is described as moderate. I may not be alone in being baffled by the conclusions drawn from these results: "Efficacy was similar in the two groups"; "Overall both drugs proved to be effective antidepressants over the six-week trial..."; "The apparent efficacy of fluoxetine..."; "... both drugs proved equally efficacious"; "... the absolute usefulness of both drugs can only be assumed".

With the possible exception of the last of these statements, none of them (*pace* the pharmaceutical industry) is warranted by the evidence presented. Perhaps the most convincing result was that amitriptyline gave patients dry mouths and made them fat; fluoxetine made them sick. This seems a good example of the "me-too" variety of drug trial. A placebo group was omitted on ethical grounds. Similar grounds might have been invoked for the omission of the conclusions.

Tuberous Sclerosis and Psychosis

Sir: Dennis & Hunt (*Journal*, September 1987, **150**, 413–414) have recently drawn attention to two case reports in which tuberous sclerosis in associated with psychotic symptomatology (Lawlor & Maurer, *Journal*, March 1987, **150**, 396–397; Clarke *et al*, *Journal*, May 1987, **150**, 702–703). In addition, they refer to their own study of ninety children with tuberous sclerosis, over half of whom demonstrated psychotic behaviours (predominantly autistic or hyperkinetic) (Hunt & Dennis, 1987). They propose that profound language delay, severe impairment of social interactions, hyperkinesis and sleep disturbance constitute a behavioural phenotype. They believe that this occurs so frequently as to be included within the diagnostic criteria for tuberous sclerosis.

Within the field of mental handicap, there are few specific organic disorders which are associated with specific psychiatric disorders. Exceptions might include organic mental states in Down's syndrome, self-mutilation in Lesch-Nyhan and Cornelia de Lange syndromes, autistic-like symptomatology in Rett's syndrome, and perhaps a few others.

The problem of associating tuberous sclerosis with autistic symptoms is of interest, but difficult, as it raises our uncertainty over the aetiology of autism itself, although this is presumably the result of some organic lesion. The association really resolves itself around two questions: is tuberous sclerosis *directly* associated with autistic symptoms? Or does it frequently give rise to degrees of mental handicap, which are themselves frequently associated with autistic symptoms?

The authors need to show that, having controlled for degrees of mental handicap, patients with tuberous sclerosis are more likely to develop autistic symptoms than other groups of brain-damaged individuals. Unless this is done, the suggestion that autistic symptoms are specifically applicable to individuals with tuberous sclerosis, any more than to patients with, say, hydrocephalus, may be entirely spurious.

Comparative Trial of a New Antidepressant

SIR: Few would argue with the point raised by Dunn (*Journal*, August 1987, **151**, 269) and Thompson (*Journal*, November 1987, **151**, 702–703) that a comparison of a new antidepressant with a placebo to establish that some efficacy exists is desirable. Clearly, ethical issues are a problem, and there is an extensive literature highlighting these (Klerman, 1986; Rickels, 1986). Practical issues are also a factor, and in a current clinical trial involving placebo control an eminent colleague withdrew his involvement because he felt that every patient should receive an active compound.

Studies previously carried out comparing fluoxetine, a tricyclic antidepressant, and a placebo (Stark & Hardison, 1985; Colin & Wilcox, 1985) confirmed that fluoxetine was more effective than placebo.

My study (Levine *et al, Journal*, May 1987, **150**, 653–655) was carried out to establish further evidence of efficacy and to compare the occurrence of side-effects with those of imipramine. The numbers involved allowed for any significant difference to be discriminated. A minimum score on the HRSD of 17 permitted less severe cases to be included. The suggestion by Thompson that 75 mg of a tricyclic antidepressant is "well accepted to be inadequate" is surely an idiosyncratic view, and is at variance with established practice over almost 30 years. Perhaps the as yet unpublished paper quoted in his letter will inform us otherwise.

The need for new antidepressants clearly exists when present compounds are only marginally more effective than placebo at any dose level, and future research will hopefully not be influenced by the "overcrowded market".

Depressed Mood After Stroke

SIR: For Wade *et al* (*Journal*, August 1987, **151**, 200–205) to compare their finding that 20% of their stroke patients were definitely depressed and 10% probably depressed with Bergmann's (1982) reported rate of 4.4% for depressive illness and neurosis in 360 elderly women is of doubtful relevance. Reported rates of depression in community studies of the elderly vary enormously, and one could equally well argue on the basis of comparison with the work of Zung (1967) or Stenback (1979) that stroke protects against depression, as both these studies can be interpreted as demonstrating depression in well over 40% of elderly subjects. It is possible to quote studies which purport to show rates of depression in old age which vary from 48% right down to 1%. None of them help to interpret the findings of Wade *et al*, whose study is flawed by the lack of an age-matched control group, and the use of an instrument which was not developed in order to measure depression in stroke victims with an mean age of 70 but to measure the severity of the depressive syndrome in a group of patients already diagnosed as depressed whose mean age was in the mid-forties (Snaith *et al*, 1971).

SIR: We thank Ames for stressing that the Wakefield Self-Assessment Depression Inventory was not developed for use with elderly people, and for pointing out that we did not have an age-matched control population. We discussed both points in the original paper, although we acknowledge that we did not refer to the population studies he mentioned.

The study was under several contraints. In particular, we were not aware of any simple measure of depression which could be used in a large number of elderly people. Indeed, we still do not know of any such index. There was not time within the constraints of this study to identify and assess a similar group of control patients. This study is purely descriptive, and generates many hypotheses needing further investigation. We sincerely hope that the two major weak links identified by Ames will be investigated in future.

Long-Term Psychiatric Patients in the Community

Sir: The debate concerning the wisdom of continuing psychiatric hospital closures and the advantages of community care ultimately rests on the evidence, which at present is scanty. Bell *et al* (*Journal,* August 1987, **151,** 275) have investigated this issue. The interpretation of their data is really a question of one's outlook, but whether one chooses to describe a cup as half empty or half full, it certainly will not be running over.

Out of 25 patients who had been selected for discharge over an 11-year period, and who had been in hospital for at least two years, we are advised that "half" had lost contact with psychiatric services, one was in prison and four were dead. It is true that the dead had all been "at an advanced age", but one might question the wisdom of relocation in these circumstances. Of the remainder, we are advised that five had been readmitted to hospital, one indefinitely, and that when interviewed, in a semi-structured way, "a roughly equal" proportion of the remaining population who were still in touch with psychiatric services were leading "somewhat discontented lives". The authors place a generally optimistic interpretation on this data.

We compared two well-supported out-patient groups with long-stay hospitalised patients and found that the in-patient groups had a better quality of life on a number of measures. This was despite the fact that in one of the hospitalised groups the patients were significantly older than the comparison out-patient group.

Two groups of in-patients, at St Mary's Hospital, Stannington, Northumberland ($n=40$) and Friern Hospital, in North London ($n=23$), were interviewed, together with out-patients from both hospitals ($n=40$, St Mary's; $n=16$, Friern). All the out-patients were actively supported by community nurses. The interviews were conducted according to a prepared schedule that had been piloted, modified, and discussed with the nurses prior to use. The nurses, including community psychiatric nurses, held a variety of views on the intended transition to community care.

The Friern in-patients were significantly older than the out-patients ($U=66.5$, $P<0.001$) (in-patients, range=37–73 years, mean=56.5, s.d.=11.2; out-patients, range=20–64 years, mean=40.9, s.d.=13.77) but were carefully matched for age and sex in the St Mary's groups (in-patients, range=23–77 years, mean=51.3, s.d.=15.14; out-patients, range=24–73, mean=50.4, s.d.=13.86).

In all, we enquired into 20 indicators of quality of life. Hospitalised patients were significantly advantaged (Mann-Whitney, two-tailed probabilities) in terms of attending social gatherings ($U=550$, St Mary's; $U=107.5$, Friern; $P<0.05$, both groups), going to places of entertainment ($U=242$, $P<0.001$, St Mary's), the number of meals per week ($U=24$, $P<0.001$, Friern), the number of hot meals ($U=154$, $P<0.001$, St Mary's; $U=26.5$, $P<0.001$, Friern), and the number of baths per week ($U=481.5$, $P<0.005$, St Mary's). As might be expected, the in-patients were also advantaged in the amount of time they spent in rehabilitation programmes ($U=260$, $P<0.001$, St Mary's), and in passive amusements ($U=585$, $P<0.05$, St Mary's; $U=103$, $P<0.05$, Friern, watching TV; $U=479$, $P<0.005$, listening to the radio at St Mary's). However, if contacts with nursing, medical, and paramedical staff are disregarded, the Friern in-patients enjoyed less company ($U=275$, $P<0.01$), which might reflect their advanced age, and they attentively listened less to the radio ($U=287.5$, $P<0.005$). In other respects the groups were comparable.

Our study, which we hope to report more fully, causes us to wonder whether the intended closure of the two hospitals will be entirely advantageous to all our patients. We are incompletely reassured by the findings of Bell *et al* in a selected population.

We thank the nursing staff at St Mary's and Friern Hospitals for their help in data collection.

Pseudo-AIDS, AIDS Panic or AIDS Phobia?

SIR: Miller *et al* (*Journal,* May 1985, **146,** 550–551) reported on two men with excessive concern about AIDS: one had a diagnosis of anxiety neurosis, and the other had a diagnosis of depressive illness. The authors argued that this was a new psychiatric condition arising from the AIDS epidemic and coined the term 'pseudo-AIDS'.

Since the publication of this article, similar conditions have been described and called in turn 'AIDS-induced psychogenic state' (O'Brien & Hassanyeh, *Journal,* July 1985, **146,** 91); 'AIDS phobia' (Jacob *et al, Journal,* March 1987, **150,** 412); or 'AIDS panic' (Windgassen & Soni, *Journal,* July 1987, **151,** 126–127).

All of these definitions seem to place AIDS in a causative role in creating such conditions. We join O'Brien (*Journal,* July 1987, **151,** 127) in stating that what is important in patients presenting with excessive concern about AIDS, but without the disease, is not AIDS itself, but the underlying psychiatric state.

The common feature of the psychiatric illness, with AIDS concern as a symptom, is hypochondriasis. In hypochondriasis, the illness of which the sufferer has fearful apprehension is usually inherently frightening and often stigmatised by society, classical examples being syphilis and cancer. In addition, the sufferer is often someone who has already been brought into psychological contact with the disease, e.g. by a relative, friend, or even health workers. The fear of AIDS meets all of these criteria (Thompson & Riccio, 1987). Indeed, Miller (1987) has stated that such patients are similar to those with worries about other venereal diseases.

Fear of AIDS may also be a part of the content of any psychopathology, such as obsessional disorders (Goldmeier, 1987), affective disorders (Lippert, 1986), schizophrenia (Rapport, 1985), or monosymptomatic hypochondriacal delusional states (Lippert, 1986). In such cases of severe psychiatric disorders, the fact that AIDS is the content or object of the psychopathology is of little significance in the diagnosis or treatment of the disorder, which should be carried out in the usual way (Thompson & Riccio, 1987).

Finally, it can be argued that the term 'AIDS phobia' is misleading. The modern definition of phobia requires the presence not only of irrational fear of a harmless stimulus, but also avoidance of that stimulus. Thus, to be genuinely AIDS phobic, the patient would be required to irrationally avoid AIDS – almost a paradox, except when there is avoidance of AIDS even as a thought or a topic of conversation. The term 'AIDS phobia' is therefore a misnomer, since the patients to whom the term is most applied, i.e. the 'worried well', show little or no tendency to irrationally avoid AIDS.

Neuroleptic Malignant Syndrome (NMS): A Misnomer?

SIR: Kellam's review (*Journal,* June 1987, **150,** 752–759) is apt. Perhaps it is time for the nomenclature of so-called NMS to be revised. Besides its possible occurrence before the advent of neuroleptics, it is now well reported that non-neuroleptics are also implicated, e.g. tetrabenazine (Burke *et al,* 1981), levo-dopa (Henderson & Wooten, 1981), and dothiepine (Grant, 1984). One case of NMS was attributed to metoclopramide combined with cimetidine (Destee *et al,* 1981), another was seen in an overdose of benzodiazepines, phenelzine, dothiepin, and alcohol (Ritchie, 1983), and yet another was attributed to amphetamines (Chayasirisobhan *et al,* 1983). The current restricted nomenclature, using the word neuroleptic, is not an accurate reflection of current facts and predisposes those not familiar with the literature to a sense of false security.

As most cases appear to occur in the context of treatment procedures, "Iatrogenic malignant syndrome" might be more appropriate, but we would guess that this would prove unpopular, particularly in the context of explaining the condition to patients, their relatives, or possibly their legal advisers.

Ritchie, P. (1983) Neuroleptic malignant syndrome. *British Medical Journal*, **287**, 561.

Sir: Kellam (*Journal*, June 1987, **150**, 752–759) has included Stauder's lethal catatonia on inadequate grounds, quoting Mann *et al* (1986), who consider NMS to be a neuroleptic-induced iatrogenic form of lethal catatonia. A similar opinion has also been expressed by Lindesay (1986), who perceived NMS as a hybrid of iatrogenic disorder and mis-diagnosed lethal catatonia. Lindesay suggested that lethal catatonia represents an idiopathic form of the disorder, whereas NMS may represent an iatrogenic form.

While not rejecting these opinions outright, it has to be kept in mind that the so-called lethal catatonia has only face validity as a nosological entity. There have been no well-planned prospective studies on its descriptive validity, construct validity, or predictive validity. Whatever information is available at the moment on lethal catatonia is a compilation of anecdotal reports such as the reviews by Mann *et al* (1986) and Kellam. Moreover, lethal catatonia is not mentioned in the current diagnostic and classification systems (DSM-III, ICD–9), and most psychiatrists no longer diagnose Stauder's lethal catatonia. Indeed, the term 'catatonia' is obsolete and confusing and should be elimintPed from psychiatric terminology (*Lancet*, 1986), despite recent attempts to rehabilitate it (Barnes *et al*, 1986; Mann *et al*, 1986).

A superficial clinical resemblance between an iatrogenic syndrome and an entity of historical importance should not be grounds to contest the nosological status of NMS.

Sir: I agree with Singh & Maguire. Possibly if a new name for the syndrome is required it should be simply descriptive, as the aetiology remains obscure. I would suggest 'pyrexial catatonia'.

I am grateful to Adityan Jee for directing me to the invaluable article by Barnes *et al.* I would agree that 'catatonia', and especially its 'acute lethal' sub-type, only have face validity as clinical entities. I am not sure that any of the ICD–9 or DSM–III categories have much more. If we were to restrict ourselves to those categories whose validity had been demonstrated by well-planned prospective studies on their descriptive validity, construct validity, and predictive validity we should have few diagnostic entities left to use, either clinically or for further study.

My impression remains that a syndrome marked by rigidity and abnormalities of movement (catatonia) has been observed by several generations of psychiatrists, probably since they started to record their observations systematically. It was most often associated with other symptoms of what we now call schizophrenia, but has become rare since the advent of neuroleptic drugs. Occasionally it was associated with a fulminating course and death in hyperpyrexia. If this syndrome were to occur now it would usually do so in a patient already on neuroleptics, which would account for the Parkinsonian features now commonly seen and thus be indistinguishable from the neuroleptic malignant syndrome. I am therefore prepared to question whether neuroleptics or the other well-documented changes in dopaminergic drive, such as stopping L-dopa, are always to blame for the syndrome. I am currently enquiring of Barnes *et al* whether their idiopathic cases were pyrexial, in the hope that they may have recorded neuroleptic malignant syndrome in a drug-free patient.

The syndrome is probably stuck with its current name. My thesis is that we need to remind ourselves that we are not certain of either the implied aetiology or outcome. Vigorous treatment is to be encouraged in view of the reduction in mortality which can apparently be expected.

Recent work by Addonizio *et al* (1986) suggested the presence of a partial NMS in eight patients, as well as the full syndrome in two patients, out of a series of 82. All showed pyrexia and extra-pyramidal rigidity or tremor, and in the partial cases the symptoms remitted without the neuroleptics being stopped. I hope to repeat this work on a larger series to see if a mild pyrexia is common in patients receiving neuroleptics and showing extra-pyramidal side-effects.

Finally, I should like to retract my statement that neuroleptic malignant syndrome is not mentioned in any British textbook (see O'Shea & Falvey, 1985).

Edinburgh Post-natal Depression Scale

SIR: Cox *et al* (*Journal*, June 1987, **150**, 782–786) have produced a concise instrument for detecting post-natal depression. I would question the inclusion of question seven in its present format. Probably the majority of new mothers experience sleepless nights for many weeks, because neonates generally take some time learning to sleep through the night. For such people, it might prove difficult to answer this question, which implies that unhappiness is the only cause for their insomnia. Rephrasing the question as follows might help:

"I have been so unhappy that I have had difficulty sleeping, even when my baby has been quiet and the opportunity for sleep was there...".

G. E. VINCENTI

The Duchess of Kent's Military Hospital
Catterick Garrison
North Yorkshire DL9 4DF

SIR: Vincenti has drawn attention to the central dilemma of the validity of established self-report mood questionnaires when administered to pregnant or puerperal women and to our attempt to overcome these difficulties.

The main problem which was discussed in our paper (*Journal*, June 1987, **150**, 782–786) is that certain somatic symptoms, such as weight loss or palpitations, may be caused by the physiological changes of childbearing as well as by a mood disturbance. The wording of the questionnaire items may also need to take into account the particular social circumstances of the mother and the incessant demands that may be made on her. The Edinburgh Post-natal Depression Scale (EPDS) was developed to reduce these ambiguities as far as possible.

Because many mothers experience sleepless nights for many weeks after childbirth, the sleep item (item 7), "I have been so unhappy that I have had difficulty sleeping", was worded to detect those mothers whose sleep difficulty was secondary to a mood disturbance and not caused *directly* by a noisy baby or by a restless partner.

The correlation matrix (available on request) between the 10 items on the EPDS confirmed that we had been successful in this endeavour. The sleep item had its highest correlations ($r = 0.52$) with item 3 ("I have blamed myself unnecessarily when things went wrong") and item 8 ("I have been feeling sad or miserable"), which would indicate that this item is detecting women whose sleep difficulties relate to their depression.

The modification suggested by Vincenti is, in our opinion, unlikely to be an improvement and might cause yet further problems; for example, what *are* the requirements for "the opportunity to sleep" – a comfortable bed, or perhaps a quiet partner?

Predictions of Outcome in Depressive Illness

SIR: Eagles (*Journal*, May 1987, **150**, 715) appears to claim that we were unjustified in assuming that patients presenting for admission to hospital on clinical grounds were more likely to be depressed than those who remained in the community (*Journal*, January 1987, **150**, 43–48). We would like to hear the evidence supporting his rather idiosyncratic view.

We will answer Eagles' points seriatim. He observes that the sample was not "normally distributed" on the Newcastle Scale. However, elsewhere in the article, we clearly showed that there was evidence of discontinuity in the distribution.

He questioned the representative nature of the sample. However, we made no claim that the sample was representative of anything other than severely depressed patients. We made this clear on p. 46, second column: "we were probably not looking at a random sample of the general population, sources of potential bias being the mode of referral to hospital and the criteria of selection for the trials". Moreover, this was confirmed by the use of the Newcastle Scale worked out for use with similar in-patients.

We accept that there is a distinction between treatment response and outcome, and this may become important in the remoter outcome period. However, in the short term the two are virtually identical. Differences might arise in the longer term, and outcome measures could provide further criteria for determining whether there is a binary distribution of outcome or, whatever the follow-up measures employed, this had a unimodal distribution. However, this was outside the modest remit of our own study, although it could be looked at in the future. Thus the inference drawn by Eagles that "these findings provide no convincing evidence for the dualist theory of the classification of depressive illness' is clearly not supported by the evidence and is therefore inappropriate.

The Hungerford Massacre and its Aftermath

Sir: The above hypereredic* episode has received world-wide publicity. The unanticipated consequences of such attention seem worthy of closer observation, as does the possibility of prevention in some instances of this type of explosive behaviour.

During the 1950s and 1960s I examined hypereredic individuals categorised in this area as 'amok runners'. They came from among peoples of three grades of technological development: the Melanesians of Papua New Guinea, the Chinese in Singapore, and the Europeans resident in Australasia (Burton-Bradley, 1968, 1972). Since that time further instances have surfaced in this area at the rate of approximately one every 18 months. Although culturally variable, there is a hard-core symptomatology in all of them, based on the self-defined unrelieved insult. There are four discrete periods: (a) a prodromal brooding, during which a resolution may be effected if circumstances permit; (b) explosive homicidal outburst; (c) continuing homicidal drive; and (d) a retrospective claim of amnesia by the ones who survive.

Case Reports: (i) A 35-year-old Caucasian public servant had received no promotion for 10 years. He wrote me a letter in 1967 outlining his claim of differential treatment. He stated that he had been continually overlooked, that colleagues with the same or lesser qualifications had been promoted, and that he had been railroaded into a dead-end position. He declared his empathy with, and total acceptance of, the solution adopted by a laboratory technician in remote Pennsylvania, USA, who had recently ran amok killing six people and wounding six others. This had been reported in great detail in the weekly newspaper. The victims were people in authority over him. I asked the public servant to come and see me, and during the course of interview I detected oversensitivity coupled with anxiety and anger. I formed the opinion that he had a diminished capacity to select and control alternative forms of behaviour. There was, I felt, a serious risk that he would act out the Pennsylvania model. I conferred with his superiors, and it transpired that his promotion was in fact being processed, but at a slow bureaucratic rate. This was speeded up, and the would-be amok runner informed, with dramatic effect in eliminating his brooding. When examined again two years later he was free of all symptoms.

(ii) Another Caucasian amok runner, who was killed during the period of his episode, left behind a letter showing how he had modelled his plans on a similar tragedy which took place in remote Canada one month earlier. He had read about it in the newspaper. He had been rated by his victims as a "humbug". He acted out the Canadian model.

These brief observations show that the physician, close acquaintance, or other person in contact with an adult male (usually living alone) who outlines his disaffections in the above fashion should be alerted. The proposed ban on certain classes of firearms, admirable as it may well be, is based on a response to public expectation and not necessarily on fact. It will do little to eliminate such episodes, and gives the impression of seeking a solution merely by closing the door after the horse has bolted. Also, it is unlikely that much help will, or could be, obtained from the media, but such bodies should be adequately informed. But is psychiatric expertise being fully utilised?

Hypereredism: a morbid state of hostile tension, following provocation, sometimes leading to explosive behaviour out of proportion to the circumstances.

Behaviour Disorder in Childhood Re-assessed

Sir: We have completed a pilot study of one year's intake of 207 children as new out-patients to a hospital-based department of child and adolescent psychiatry. At follow-up, 16 months after the intake began, there were 67 cases closed; these were evaluated by two clinicians, mutually blind to each other's assessments. The assessments were made from recordings of the parents' overall description of their children's present state. Inter-observer disagreement occurred in 5 out of the 46 cases assessed by both.

The interesting result was that response to intervention was greatest with behaviour disorder (76%) and least with neurotic disorder (57%). This is opposite to the generally held view, supported by numerous studies (West & Farrington, 1977; Mulligan *et al*, 1963; Richman *et al*, 1982), that behaviour disorder is difficult to treat and has a poorer prognosis than childhood neurosis (Rutter, 1972; Kovaks *et al*, 1984).

Perhaps the introduction of a family therapy approach (which always involves the father in our clinic) changes the prognosis compared with more traditional therapeutic approaches. A three-year follow-up of all 207 cases will be completed shortly

Indecent Exposure – A Report of a Female

SIR: Indecent exposure is a rare problem in women (O'Connor, 1987), and the few reported cases are generally associated with factors such as hypomanic episodes or alcohol use. We report an ex-nun with a history of inappropriate sexualisation as a young child, referred because of genital exposure.

Case Report: A 36-year-old sales assistant was referred because of feeling depressed and a six-year history of genital exposure, usually to authority figures: for example, the mother superior while living in a convent, and the priest running a therapy centre. She had also exposed in order to get attention when feeling miserable and lonely. The exposure was planned; she would enjoy a response of shock and anger and lie on the floor kicking her legs, talking in a babyish fashion, and hoping to be smacked. She would also make repeated telephone calls, and haunt the front door of her victims (usually women).

The patient's mother had no time for talking, playing, or cuddling with her four children (her husband was a violent man and a heavy drinker), and would masturbate her children to comfort them if they were upset; their only bodily contact was smacking. Her younger brother was impotent as an adult, and our patient had never had a sexual relationship, but enjoyed looking at other women's bodies.

We aimed to help the patient to make friends and to relate normally in a therapeutic community of patients with mainly long-term neuroses, while continuing at work. She managed to keep this job, but made no friends and continued to expose to senior nursing and medical staff.

This report illustrates the lasting damage of inappropriate sexualisation in a young child (Mzarek & Kempe, 1981). She had no experience of affectionate non-sexual handling, and attached erotic sensations to non-sexual infantile behaviour and so regressed in this way. This was sexual abuse from stressed parents who did not derive sexual gratification themselves but were in need of help with their family. Early intervention in such families is very important (Werner, 1985).

Mania Following Head Injury

SIR: We read the report by Clarke & Davison, (*Journal*, June 1987, **150**, 841–844) and would like to report another example.

Case Report: A 38-year-old self-employed married businessman was admitted in May 1987 for investigation and assessment in respect of abnormal behaviour following severe head injury.

His personality type was of the overactive, ambitious, and aggressive type, with an above-average IQ – the epitome of the Type A personality. He ran two businesses simultaneously, and his hobby was competitive cycling. There was no past history or family history of psychiatric illness.

In December 1986 he fell from his push-bike and was found unconscious in the road. He showed signs of a right sub-dural haematoma, and was transferred to a neurosurgical department where CT scan confirmed this. An emergency craniotomy and evacuation of extra-dural and sub-dural clot was performed. At operation, laceration of the right temporal lobe was noted. His post-operative course was stormy – he was unconscious for several days, and then required sedation for restlessness and aggression. He was treated with phenytoin and phenobarbitone. He subsequently made a reasonable recovery physically, with only a persistent right-sided facial nerve palsy and hemianopia.

However, on his return home (three weeks after the injury) he developed markedly abnormal behaviour, with over-activity, outbursts of unprovoked aggression, disinhibition, extreme emotional lability, grandiosity, and irritability. The extent of these symptoms severely threatened his marriage and his business. At this time he refused tranquillisers or psychiatric treatment.

Some weeks later he accepted psychiatric assessment. On admission he presented as an intelligent man, mildly elated in mood, garrulous, and obsessed with his physical fitness. He had the fixed idea that his problems were entirely due to an abnormal glycogen metabolism which he could cure himself by strict dieting. He was physically overactive, but co-operative.

His EEG showed "abnormal asymmetrical activity and a persistent excess of slow activity over the right anterior to mid temporal region". CT brain scan was abnormal, showing "contusion and ischaemia at the right temporal and parietal regions and severe right temporal atrophy". Psychometric testing showed strong evidence of impairment of functioning at the anterior portion of the right temporal lobe (Rey Osterrieth) and also of the frontal lobe (verbal fluency and behaviour on the Wisconsin). It is likely that his frontal lobe pathology is *contre coup* injury, and the right temporal and parietal signs correlate well with this head injury.

He is now back at work, his mood has improved and stabilised, and he has developed some insight, although he continues to believe that his psychological problems have been due entirely to problems of glycogen metabolism. His wife says he is still "overdoing it", but he is no longer frankly hypomanic.

Acute Psychotic Episode Caused by the Abuse of Phensedyl

Sir: Following the recent publications concerning ephedrine abuse and ephedrine psychosis (Whitehouse & Duncan, *Journal*, February 1987, **150**, 258–261; Jelley, *Journal*, September 1987, **151**, 418–419), we report a case of phensedyl abuse precipitating an acute psychotic episode.

Case Report: A 49-year-old asthmatic married woman was admitted to our psychiatric unit as an emergency in an agitated and excitable state. She was talking non-stop with some incoherence, was visually hallucinating, said that she was seeing "white spots", and was suspected of hearing voices. She thought that thoughts were being put into her mind and "made her do things", and was disoriented in time, getting the day, month, and year wrong, but was oriented to person and place. She had to be sedated because of her excitability, especially at night, and the psychotic symptoms and disorientation disappeared 48 hours later, at which point the medication was discontinued. Interview 24 hours later confirmed the visual hallucinations and thought insertion, but not the auditory hallucinations. In addition, she described experiencing something like thought broadcasting and passivity feelings. The patient was able to remember most of the period of her delirium with very minor gaps in detail. She stayed in hospital for the next five days and remained symptom-free with no medication.

Her history of phensedyl abuse dated back about 10 years. She remained vague about the amount she consumed, but on checking with her husband it appeared that she had been drinking 3–4 bottles per week. However, the week before her admission she had consumed a larger amount than usual. She also had a history of alcohol abuse, but no other psychiatric history.

Compensation Psychosis

Sir: In describing a case of compensation psychosis, White *et al* (*Journal*, May 1987, **150**, 692–694) highlight a topic of growing importance. We report another case of psychosis in the context of compensation, also complicated by bereavement.

Case Report: Our patient was a 36-year-old plumber. Two years previously his wife had died unexpectedly while in hospital, leaving him with three young children. He soon began legal proceedings against the Health Authority concerned, and appeared unable to mourn his wife's death. Fifteen months later his solicitor sought a psychiatric opinion because of anxiety about his mental health. He presented with a two-month history of depressive symptoms with prominent biological features.

His mother killed herself when he was aged 7, and his elder brother had also committed suicide three years previously. A second brother and his cousin were both victims of homicide. The patient had suffered a major depressive illness three years before, following his brothers death, and this had responded to out-patient treatment with antidepressants. His premorbid personality was extroverted.

On examination he was severely depressed, perplexed, and held the delusional belief that he, and not the hospital, was responsible for his wife's death. He also believed that psychiatrists knew this and were in league with his wife's family to punish him. He was admitted and treated with amitriptyline and chlorpromazine. Suicidal ideas and impulses emerged, and he required intensive nursing for a month. Over the next six months his illness followed a protracted and fluctuating course. Although no longer severely depressed, he still believes that he will not be well until the Health Authority is successfully sued, thus absolving him of all blame.

We think he has had a morbid grief reaction complicated by a psychotic depression in which compensation could be a maintaining factor. We are not aware of any reports of such cases in the UK literature, but this may become an increasingly common phenomenon in the wake of tragedies such as Bradford and Zeebrugge. Our patient, like many survivors of those tragedies, has suffered multiple losses and is also involved in a compensation claim.

Rosenblatt (1983) suggests that lawyers involved with this client group should be aware of their special needs, and that "the recurrent review of the loss brought about by involvement in a suit may disrupt the normal detaching process, thus leading to a morbid grief reaction". Litigation may also be an increasingly fashionable style of response to such losses. While it is tempting to speculate further, there remains little systematic evidence on which to base important clinical decisions about management. This is an area which merits further study.

Consent to Investigation

SIR: The philosophy of the Mental Health Act 1983 was to "strengthen the rights and safeguard the liberties of the mentally disordered" (Bluglass, 1984). This ethos emerged in the innovative consent-to-treatment area of the Act. However, the relevant sections are specific in nature, and thus situations could arise which are not dealt with by the Act. The following case report illustrates such a problem in organising investigations.

Case report: A 47-year-old housewife was admitted under Section 2 of the Mental Health Act 1983, suffering from her first psychiatric illness of an episode of typical agitated depression. After a four-week trial of amitriptyline and chlorpromazine there was no improvement, and ECT was prescribed. The patient refused consent to this treatment, and so Section 3 was applied. The Mental Health Commissioner agreed to a course of ECT, as the patient was unable to eat or drink. Two months later there was a little improvement, but a request for a second course of ECT was declined by the Commissioner on the grounds that even though the patient remained ill the situation was no longer life-threatening.

Throughout the hospital stay the patient refused investigations. Consequently, even though she was not responding to medication or ECT, an organic cause for her illness could not be excluded because of her non-cooperation. Enquiries were made to discover whether investigations could be performed without consent. The Mental Health Commission stated that the issue was not covered by the Act and a medical defence organisation advised us not to proceed, as so doing would probably constitute a battery.

Half-way through the duration of the patient's treatment under Section 3 the Commissioner returned to decide if the patient could be given medication against her consent. A treatment plan was provided suggesting a trial of lithium, in view of the failure to respond to antidepressants alone. However, if approved, the legality of forcing investigations to monitor serum lithium was not known. Further correspondence with a medical defence organisation revealed that they too were unsure. Fortunately, the Commissioner resolved the problem by agreeing to the treatment plan and to the investigation of the patient. Necessary blood tests were therefore taken, and an EEG was performed. The latter was reported as normal, and the patient responded well to the trial of lithium.

The requirement to consult Mental Health Commissioners in order to plan the treatment of detained patients is appropriate to safeguard their liberty. However, investigations are an important component of the management, but as they are not dealt with specifically by the Act they are covered by common law, which permits procedures only to be performed against or without consent if they are life-saving. Investigations are rarely life-saving, and so necessitate consent.

The importance of investigations are highlighted by the above patient, whose unresponsiveness to treatment may have been due to an organic cause. If this had been so, then the four-month delay before the investigations were carried out could have been detrimental. Investigation for an organic cause for mental illness is important to allow appropriate management. Just as patients do not understand or consent to treatment, they may also misunderstand or be frightened by investigations.

It is surprising that this point regarding investigations did not occur during the drafting of the Act or subsequently, but this patient and the difficulties and delays encountered exemplify the need for clarification on the point. Possibly the issue of investigations could be dealt with in the same manner as treatment presently is under the Act, and be administered by the nominated Commissioners.

CORRIGENDUM

Journal, August 1987, **151**, 160–165 (Wig *et al*). The names of Jørgen Achton Nielsen and Grethe Thestrup, from the Aarhus Psychiatric Hospital, Risskov, Denmark, should be added to the list of authors.

A HUNDRED YEARS AGO

Lunacy regulations in France

In consequence of certain irregularities revealed by the investigations into the case of Baron Seillières, who, it was alleged, was improperly detained in a lunatic asylum near Paris after he recovered his mental equilibrium, the Minister of the Interior, M. Fallières, has issued a circular to all prefects directing them rigidly to obey the enactment which requires them to make periodical visits to all asylums, public or private, within their jurisdiction. It is directed that these visits should be paid unexpectedly, and not less frequently than once a quarter; that patients who desire to leave the asylum should be interviewed, and in every doubtful case subsequently subjected to a special medical inquiry; that the use of the shower-bath as a punishment should be forbidden; that the period of observation should be reduced to the shortest possible time; and that frequent transfers from one establishment to another should be discouraged.

Book Reviews

Editor: Sidney Crown

Psychology of the Self and the Treatment of Narcissism. By Richard D. Chessick. Northvale, NJ: Jason Aronson. 1985. 367 pp. $35.00.

'The psychology of the self' is the name now given to the theories and the approach to psychotherapy developed by Heinz Kohut and contained for the most part in his two books, *The Psychology of the Self* (1971) and *The Restoration of the Self* (1979). They have had an enormous influence on psychotherapists in the United States and to some extent elsewhere, and are clearly something all therapists should know about. It is not easy to read Kohut himself, and I have never been sure if it was worth taking the time and the trouble of getting to understand what he is talking about. This book will help readers to acquaint themselves with his ideas and form a personal judgement of them.

I have certainly found it fascinating to recognise how Kohut became preoccupied with narcissism and concepts of the self, which are the same issues which interest contemporary British psychoanalysts. His approach is totally different, however, and in its final version represents a turning away from psychoanalytic work.

Chessick seems to be experienced, not only as a psychiatrist and psychotherapist, but also as a philosopher. The bibliography lists 37 publications since his first in 1969, and no less than eight of these have been books. His chief preoccupation is with narcissistic disorders and borderline states, but his interests are wide and his erudition comes through clearly.

The book begins with an introduction to the concept of narcissism, via the Greek myth of Narcissus, and then quickly proceeds to review the psychoanalytic developments in this area, beginning with Freud. A fairly detailed account of Melanie Klein's views follows, and although Chessick is generally out of sympathy with Kleinian ideas he acknowledges them to be important and indeed suggests that they provide an alternative approach to some of the same issues which have occupied Kohut.

The largest and most important section of the book is the exposition of Kohut's theories, which is complicated by the fact that they changed as his ideas evolved. Chessick makes this relatively easy to follow by providing chapters on the first version, on Kohut in transition, and on the second version of the psychology of the self. These are preceeded by a discussion of the definition of the self and by a short account of the role of the self in the work of Fairbairn, Winnicott, Balint, and Laing.

It is not possible to give an account of Kohut's ideas in this short review, but the interested reader will be able to find out what Kohut means by a number of terms which are central to the understanding of his theories. Thus 'Narcissistic transference', 'empathy', 'selfobject', 'the grandiose self', 'the idealised parental image', 'the bipolar self', 'the varieties of mirror transference', 'narcissistic rage', and many other terms are clearly described and their importance discussed.

Kohut suggests that Freud presented us with a model of *guilty man*, so that psychoanalysis became preoccupied with conflict between love and hate and its consequences. The analyst becomes the representative of the patient's conscience, and instead of helping him, persecutes him. Kohut presents his model of the individual as *tragic man*. In his view the central issue facing the patient is the way he reacts to his failure to realise his ambitions and ideals. The cause of mental disorder is primarily put down to the failure of the parents to empathically understand and encourage the child's narcissism, and the therapist attempts to put this right by providing such understanding.

While most psychoanalysts consider that omnipotence, narcissism, and self-idealisation are defensive manoevres to deal with deeply disturbing experiences, Kohut emphasises the normal need for positive affirmation, which he considers leads to a proper sense of a cohesive self. He relates this to the glimmer in the mother's eye as she watches her baby with approval and admiration, and he teaches the therapist to allow similar idealising transferences to develop, in which the patient feels he can stimulate admiration and excitement in the therapist.

Further sections of this book present clinical material discussing some of Kohut's patients as well as those of the author, and these help the reader to apply the concepts clinically. There are also discussions of diagnosis and nosology, and a comparison with French views of the self as presented by Satre, Lacan, and Foucault. A special chapter on criticisms of Kohut is also useful, and although the author is clearly impressed with his work he is quite capable of discussing the problems it raises.

This is a very helpful book and a model of good exposition. Whether the reader will want to go on and study Kohut will depend on his approach to psychotherapy. Even those who prefer a psychoanalytic understanding will, however, find it useful and will be led to reconsider some of their own views as a result.

John Steiner, *Consultant Psychotherapist, Tavistock Clinic*

Drugs and Sexual Function: A Pharmacological Approach. By M. A. DAVIES and A. D'MELLO. Harpenden: Ridge Publications. 1986. 66 pp. £4.00.

This short booklet is intended to be read by a large group, including doctors, pharmacists, pharmacologists, research workers, medical teachers, and students. It is unlikely that any text could appeal to all of these equally, and I suspect that it will be read mostly by students, although they may well be put off by the price. The authors are extremely modest and do not indicate their place of work or qualifications. They give a good account of the physiology of sexual function in the first third of the book, followed by an account of the ways in which drugs can affect functioning in different ways. This is useful because it emphasises that it is not always easy to interpret the effects of drugs on sexual function. The final part of the book outlines the actual effects of drugs on sexual function, and this is summarised in tabular form at the end of the book. Much of the information was obtained from a computer search of the literature between 1979 and 1984 and is reasonably up to date.

I found the text easy to follow, although its style was a little journalistic. The clear diagrams aid understanding, and some of them are very good. There is little doubt that the authors have identified an important problem, and one which is not dealt with particularly well elsewhere. I hope the book will succeed in reaching a wide audience, and it is a pity that they have not been able to persuade their publishers, who appear to be new to the medical field, to market the book at a lower price to aid sales.

PETER TYRER, *Consultant Psychiatrist, Mapperley Hospital, Nottingham*

Suicide in Adolescence. Edited by R. F. W. DIEKSTRA and K. HAWTON. Dordrecht, The Netherlands: Kluwer Academic Publishers. 1987. 196 pp. Dfl. 100.00, $43.50, £27.95.

This is a valuable book which will disabuse anyone who believes suicide is the prerogative of the elderly. The authors, each an authority on suicide in adolescence, have provided ten chapters organised into five themes: the epidemiology of suicide in the young; personal factors associated with the phenomenon (by means of an illuminating case history); the principles of assessment and treatment; the inter-relationship between their families and the young who kill themselves; and schemes for prevention.

There is a good balance, in terms of length and style, among the chapters, and each author writes lucidly and with authority. They are careful to differentiate between what are their own personal opinions and what are more widely established empirical findings.

The only disappointing features of the book are certain lapses in presentation. A few of the figures are a challenge to the eye. An incorrect figure has been presented in the text, although the publishers have provided the correct one in their 'Errata'. In the latter they have also corrected two typographical errors; unfortunately, there are others which seem to have gone undetected. There is also an unwelcome lack of correspondence on occasions between the references mentioned in the text and those in the reference lists. It is a pity about these matters, because generally the book is well presented.

In summary, this book will be useful for clinicians and researchers. It highlights an important and (sadly) a growing problem. The reader is not only challenged to take the matter seriously, but given useful information and practical advice about how to deal with this problem.

DAVID A. ALEXANDER, *Senior Lecturer, University of Aberdeen, Scotland*

The Uses of Countertransference. By MICHAEL GORKIN. Northvale, NJ: Jason Aronson. 1987. 312 pp. $27.50.

Gorkin is a psychologist and practising analyst, and his book comes very much from within the psychoanalytic tradition. He traces the development of the idea of countertransference from Freud's rather sketchy description onwards. In passing, he produces the clearest explanation I have seen of that most tricky concept, projective identification. The body of the book explores the nature of the countertransference experiences which can arise in a variety of clinical circumstances, and discusses whether and how such feelings should be made use of in therapy.

The writing is clear, very full references are given, and differences and inconsistencies in the work of the various authors are discussed. The conclusions drawn suffer from the common difficulty with psychoanalytic writings that they are not systematically researched (and are perhaps unresearchable). However, we all have to struggle with the feelings our patients induce in us, and even the most dedicated opponent of analysis could learn from the direct way in which Gorkin describes such feelings.

This book deserves to be widely read and should certainly appear on the shelves of psychiatric libraries.

ERIC CROUCH, *Consultant Psychiatrist, St John's Hospital, Aylesbury*

Mental Illness in Primary Care Settings. Edited by MICHAEL SHEPHERD, GREG WILKINSON and PAUL WILLIAMS. London: Tavistock. 1986. 296 pp. £19.95.

This book documents the proceedings of a conference held at the Institute of Psychiatry in 1984, the principal objective of which was to evaluate and learn from the link between research and policy in this field. The coverage is wide, ranging from classification, screening, and treatment differences on the one hand to professional team roles and patterns of collaboration on the other. In addition, there are a number of short contributions based on experience and aspirations in other countries which, by and large, fail to relate relevant insights to the English scene. It is, however, the omissions that stand out. There is an absence of any substantial discussion of primary prevention in this apparently ideal setting, perhaps emphasising how little of practical value is known about the aetiology of psychiatric conditions. Balint, too, is mentioned but once in passing, and interviewing skills hardly at all.

Given the primary care setting, the book adopts a prior assumption of the medical model and deviates little from this. Much emphasis is given to the team approach, but little empirical evidence is presented on what is actually done by whom and, in particular, the precise skills exhibited by the various professionals. This is epitomised by the fact that one contributor asserts that the most important aspect is that a person is on the spot at the right time. Indeed, in the book there is debate about whether collaboration within or between teams depends essentially on personalities, the discriminating characteristics of which are not identified. Except when considering drug treatment effectiveness, this book does not help to differentiate the specific from non-specific factors in this field.

D. P. Forster, *Senior Lecturer in Community Medicine, University of Newcastle upon Tyne*

Parental Influences: In Health and Disease. Edited by James E. Anthony and George H. Pollock. Edinburgh: Churchill Livingstone. 1986. 531 pp. £25.70.

This book, edited by two distinguished psychoanalysts, consists of a series of psychoanalytically-orientated papers on the clinical aspects of ordinary and disturbed parenting. Topics include cross-generational influences, the parental experience, pathological parenting, and specific situations such as violence and psychosomatic disease. Much reference is made throughout to the works of Anna Freud, Winnicott, and Therese Benedek. It has the usual strengths and weaknesses of psychoanalytic writings – vivid and detailed case descriptions, but a turgid and often incomprehensible style of writing with an irritating lack of objectivity and criticism. This latter is particularly notable in the chapter by Sackin, ironically entitled "The parents of children with psychosomatic diseases: a critical review of the literature". Sackin criticises authors who espouse ideas with which he disagrees for reaching conclusions not adequately supported by their data. In contrast, he quotes in support of his arguments scores of authors, most of whom are subject to the same criticism, but the criticism is not forthcoming.

The psychoanalytically inclined will enjoy this book. With the exception of Wallerstein's excellent chapter on divorce, the rest of us would do well to look elsewhere if we are to learn more about parenting. Are we still expected to take seriously such statements as "the reason why such mothers (post-partum psychosis) are unable to recathect the baby after birth is because they are narcissistic and too fearful that 'a declaration of ownership of the baby' as a stolen penis would draw the anger and retaliation of those who regarded it as their own"?

Bryan Lask, *Consultant Psychiatrist, The Hospitals for Sick Children, London*

The Adolescent in Group and Family Therapy (2nd edn). Edited by Max Sugar. Chicago: The University of Chicago Press. 1975, 1986. 298 pp. £12.50.

This edition is a reprint, some ten years on, of the first, with an additional chapter by the editor on transference in adolescent group psychotherapy.

Each chapter describes a way of handling problems presented by adolescents according to the experience of the authors, whose expertise lies primarily within a psychoanalytical framework. The problems whose therapy is discussed range from those that present as personal problems to those seen as community based – e.g. school or ghetto problems – or related to membership of a problem family or to drug addiction.

For those to whom this book is unfamiliar, it contains timeless information about the adolescent process and the tasks of adolescence, which are presented, for the most part, in the form of clear descriptions of adolescent behaviour. Although the observations are usually presented from a psychoanalytical perspective, they are generally written in a way that would interest and inform those who do not embrace a psychoanalytical approach. The book can be recommended, provided it is read in the knowledge that the principles underlying both group and family therapy are subject to developmental change.

Dorothy H. Heard, *Consultant Psychotherapist, University of Leeds*

'Till Death Do Us Part: How Couples Stay Together. By Jeanette C. Lauer and Robert H. Lauer. New York: The Haworth Press. 1987. 192 pp. $24.95.

This book is based on questionnaire surveys of 351 marriages, some fulfilling, others not. The authors concentrate on what constitutes a successful marriage, and examine aspects such as commitment, individuality versus togetherness, conflict styles, intimacy, effective communication, "the meaning and course of true love", and managing change. Among issues raised are whether happiness really is the complete satisfaction of instinctual needs, and whether cohabitation is an adequate preparation for marriage. They conclude that in America, after experimentation with promiscuity, "marriage is back".

Research results include quotations from couples, and each section concludes with sentimental, often platitudinous, truisms such as, "Troubled as well as gratifying years may mark the course of a long-term satisfying marriage". Sub-sections called "Action guidelines" profer advice and suggestions on how to sustain a happy marriage. Much of this is schmaltz, apparently substantiated by research, presented in an ingenuous, moralising, 'Bible belt' style, using everyday language, and addressed to a "wide variety of professionals".

JAMES ATKINSON, *Consultant Psychotherapist, Cambridge*

Foundations of Contextual Therapy: Collected Papers of Ivan Boszormenyi-Nagy. By IVAN BOSZORMENYI-NAGY. New York: Brunner-Mazel. 1987. 337 pp. $35.00.

These papers, covering a period of 30 years, reflect the developing thought of one of the most original thinkers regarding the family context of mental illness.

Boszormenyi-Nagy's approach to psychotherapy is based on his appreciation of what he sees as the absolute existential reality of peoples' responsibilities and obligations to one another, especially within the family. The necessity of respecting these obligations, which the author refers to as 'relational ethics', is absolute; it cannot be ignored or postponed indefinitely without a heavy price in mental health. The individual is embedded in relationships, and, in particular, in a family matrix – the narcissist who attempts to deny this interdependence will be unfulfilled and may become ill. Arguing that a purely individualistic approach to therapy, or indeed to life itself, may be ultimately disastrous, Boszormenyi-Nagy encourages the therapist to take account of all persons involved in relations with the patient.

In working with marriages or families, the contextual therapist addresses the 'ethical' issues of fairness, trustworthiness, and entitlement. The assumption seems to be that people do have an intuitive sense of justice and fairness in personal transactions. 'Entitlement' is earned through the caring one gives to another. When this principle of justice is violated, the individual and his or her relationships become disturbed. The therapist helps all parties involved to reassess what each may expect of the other and also attempts to locate disguised forms of caring that are going on. The author talks also about 'destructive entitlement', a lack of remorse over destructive or exploitative behaviour, which results from being deprived or exploited. This is one of the main features described by Kernberg as characteristic of narcissistic disorders; interestingly, Boszormenyi-Nagy comments: "This freedom from remorse is not a psychological distortion. Tragically, it was actually earned through having been exploited. It is in consequence of a destructive reality". However, I am left wondering to what extent *unjustified* feelings of entitlement may be stoked up within certain personalities and grievances exploited by destructive parts of the mind – the book does not address this possibility.

The necessity for concern with posterity is emphasised. It is argued that it is only through a concern with future generations that one's legacy of caring received from one's parents can be repaid. The message is that an uncaring, exploitive attitude towards the world and its future is devastating to our mental health – a view which reminded me strongly of those of the psychoanalyst Donald Meltzer, expressed, for example, in his *Sexual States of Mind.*

Boszormenyi-Nagy sees his work as offering a perspective on therapeutic approaches, rather than a complete method in itself. His own earlier background was psychoanalytic, and indeed he regards an understanding of individual psychodynamics as essential. There are many aspects of mental life and relationships which these papers do not address – anxiety, for example, a basic focus of the analytic therapist, is not even listed in the index. While initially irritated by the prevalence of neologisms and unnecessarily dense writing in this collection, I was left feeling that my understanding of therapy and of human relationships had been enriched.

PHIL MOLLON, *Regional Psychologist in Psychotherapy (Top Grade), Dryden Road Hospital, Gateshead*

Therapeutic Trances: The Cooperation Principle in Ericksonian Hypnotherapy. By STEPHEN G. GILLIGAN. New York: Brunner/Mazel. 1987. 380 pp. $51.00.

Gilligan first reviews various approaches to hypnotherapy, clearly favouring the 'co-operative', or Ericksonian, approach. The basic premise is that therapy is a joint endeavour between therapist and client. Identification and use of the client's resources, rather than exploration of the past, are also central features. Symptoms may be used as the basis for trance induction.

The author reviews various theories of hypnotic trance and some of its characteristics. He then outlines the general approach of the Ericksonian hypnotherapist, and goes on to describe the 'co-operation strategies' whereby the therapist establishes rapport and prepares clients for the induction of trance. The remainder of the book describes various means of inducing trance and using it for therapeutic purposes. Gilligan quotes many clinical examples, and provides a full transcript of an induction. There is an interesting discussion of 'confusion' techniques for inducing trance.

This is a valuable account of how we may use Erickson's work in our psychotherapy. The newcomer to hypnotherapy will probably find it an insufficient guide to how to proceed, but as a supplement to practical instruction it should be invaluable. The more experienced hypnotherapist will find much that is stimulating and innovative. It is a valuable addition to the Ericksonian literature, if a little pricey.

PHILIP BARKER, *Professor of Psychiatry, University of Calgary, Canada*

Psychiatry in Primary Health Care. By S. SHARMA. Ranchi, India: Central Institute of Psychiatry. 1986. 150 pp.

It is increasingly recognised that untreated psychiatric illness constitutes a significant drain on the resources of developing countries. However, such is the magnitude of the problem that the specialised psychiatric services are quite inadequate to cope with that which is not already absorbed by traditional or religious healers. This textbook, aimed at the primary health care physician, is particularly written from an Indian perspective, although the content would be relevant in most developing countries. There is a concise but traditional exposition of the major illnesses, with some special chapters, for example on psychosocial aspects of fertility control, and some useful material on drugs, record keeping, and the organisation of mental health services. There is frequent use of flowcharts, and these are generally clear and easy to use. There is no index, which is a slight drawback. This is a useful benchbook for primary physicians in developing countries, but readers might be well advised to replace the plastic cover provided, which melted in my car in the relative cool of the current English summer.

STEPHEN W. BROWN, *Consultant, The David Lewis Centre for Epilepsy, Cheshire*

Making Contact: Uses of Language in Psychotherapy. By LESTON HAVENS. London: Harvard University Press. 1986. 201 pp. £15.75.

Havens, who is Professor of Psychiatry at the Cambridge Hospital, Harvard Medical School, discusses how he uses language in psychotherapy. His concern is to describe ways to be accurately empathic with patients. He is concerned to integrate descriptive psychiatry with psychoanalysis, social psychiatry, and existential psychiatry. He begins his book by first looking at the problem of establishing empathic contact with persons who for one reason or another are hidden from themselves and the therapist, and in consequence absent from the consultation. From this he formulates an empathic language to reach such persons, by means of various categories of statement: imitative, simple empathic, or complex empathic. He devotes much of the rest of the book to exploring issues of how to use language in the management of such persons.

He emerges as a warm and sensitive clinician whose preoccupations with the psychotherapy of more disturbed personalities have led him away from interpretation to a rather more active conversation. It is hard to know how transference issues can be dealt with in such a way of handling the patient.

Reading through his various categories of empathic statements, it seems as though he is offering the reader a series of prescriptions of language for the psychotherapeutic encounter. I wonder if empathic language can really be prescribed in this way? Surely it is something that can only be arrived at from the privacy of the psychotherapist's own experience of living and from the mutuality of each new therapeutic encounter with the patient.

P. J. SHOENBERG, *Consultant Psychotherapist, University College Hospital, London*

Psychosocial Treatment of Schizophrenia: Multidimensional Concepts, Psychological, Family, and Self-help Perspectives. Edited by JOHN S. STRAUSS, WOLFGANG BÖKER and HANS O. BRENNER. Ontario: Hans Huber. 1987. 220 pp. US$39.00.

Books based on the proceedings of conferences tend to be unsatisfactory for a variety of reasons, but this one is an exception because it contains several papers of unusual interest. In particular, Wing, Zubin, and Ciompi all contribute major pieces with important theoretical statements; all provide tabulated or numbered lists of propositions which could be valuable for teaching.

Wing specifies three conceptual levels underlying long-term management, as well as four categories of environmental influences on schizophrenic syndromes: the course of the illness, he points out, depends much on the social environment, and often requires walking a tightrope between too much and too little stimulation. However, factors that can affect the various manifestations of the disorder need to be translated into hypotheses about methods of care which can then be tested – a process that has scarcely yet begun. At the level of management he emphasises that this cannot be done successfully in the long term unless services are geographically responsible, comprehensive, and integrated. Relevant to the present Gadarene rush to extra-hospital facilities is his comment that "sheltered communities can have all the characteristics of open care, while a terraced house in an ordinary street can be like a small and isolated prison".

The veteran Zubin is determined to be optimistic and to reject chronic disability as being inherent in many cases, although this seems to strain the limits of acceptance. His vulnerability model regards the patient as being essentially well, although subject to one or more episodes of illness; the natural healing process may be impeded to varying degrees by "ecogenic forces", but enhanced by good social networks, ecological niches, or premorbid personality – which may mitigate the impact of stresses. Zubin says that outcome studies must use controls which are concordant for all important psychosocial variables, but it is far from clear how this could be done.

Ciompi lists no less than eight integrative models, and maintains that chronicity depends more on psychosocial than on genetic/biological factors, although the case for this is not strongly argued. He also proposes a three-phase model to establish connections between vulnerability and information-processing, based on Piagetian theory. It is elegantly argued, but largely translates well-known concepts into different terminology. There are also nine therapeutic principles for the psychosocial management of schizophrenia, including the suggestion that psychosocial measures may act as alternatives to medication, but the work of Leff and Hogarty does not support that view.

Other papers deal particularly with social skills training and with self-help by schizophrenics. The contributions which were originally in German show a number of translation problems, but overall this book stands out through its unusual quality.

HUGH FREEMAN, *Consultant Psychiatrist,*
Hope Hospital, Salford

A Primer of Human Behavioural Pharmacology. By ALAN POLING. New York: Plenum. 1986. 246 pp. $29.50.

The author, in his preface, writes that this book is intended to introduce principles of behavioural pharmacology to readers with little or no knowledge of the discipline but with an interest in how drugs affect human behaviour, but it is hard to know for whom the book is intended. The book is written in a lively style with each new concept being clearly defined, but once a reader's interest has been stimulated few references to more specialised textbooks are given (and where listed are, in at least one case, an out-of-date edition). The coverage of topics is varied. The section on basic pharmacology is very basic, while the chapter on clinical drug assessment touches on many topics, including the DSM–III diagnosis of schizophrenia and methods of measuring behavioural change by direct observation. Although the author graphically illustrates the measurement error inherent in different methods of observing behaviour, this can be of limited value to people embarking on clinical drug assessments when few references to methodology have been included.

This book is recommended as a stimulating introduction to the subject, but should not be regarded as a basic textbook in behavioural pharmacology, in spite of its title.

ELIZABETH GOODALL, *Research Fellow, Medical College of St Bartholomew's Hospital, London*

A Textbook of Clinical Neurophysiology. Edited by A. M. HALLIDAY, S. R. BUTLER and R. PAUL. Chichester: John Wiley. 1987. 730 pp. £32.50.

This book comprises a series of didactic lectures given at the International Congress of Electroencephalography and Clinical Neurophysiology, held in London in 1985. Distinguished clinicians and scientists were invited to lecture on specially chosen topics, so that the series formed a complete course covering all three branches of clinical neurophysiology: electroencephalography, evoked potentials, and electromyography. The speakers were asked to emphasise their views on clinical practice rather than research in progress, and texts based on those lectures have been published here. The result is a remarkable book in that it contains the views of so many international experts under one title. However, as might be expected of a volume compiled in this way, the chapters are very varied, particularly in the level of complexity addressed. They range from a section on signal averaging with instructing equations to a chapter describing the most elementary principles of nerve conduction studies. However, each contains interesting and useful information, as would be expected from this authorship.

The book has been produced and published promptly and is inexpensive (possibly to the slight detriment of one or two of the illustrations). As stated in the preface, it cannot really be regarded as a primer, and indeed there must be some question as to whether 'textbook' is the most appropriate title. It is, however, excellent value and mandatory reading for any modern clinical neurophysiologist. Presumably the sections on EEG and long latency evoked potentials would be of interest to psychiatrists.

CLARE J. FOWLER, *Consultant Clinical*
Neurophysiologist, The Middlesex Hospital and
St Bartholomew's Hospital, London

Community Clinical Psychology. Edited by HUGH C. H. KOCH. Beckenham: Croom Helm. 1986. 349 pp. £22.50.

This multi-author book has as its stated aim "To determine the main components of what clinical psychology has to offer within a community framework". It does not claim to be comprehensive overview, but covers a wide range of topics. There is an emphasis on "using psychologists' knowledge and skills that will help (other) staff". There is also an emphasis on the growing importance of prevention. The editor states that it is intended not only for those working with clients but also for managers, which is perhaps an interesting comment from a practitioner who became a manager shortly after completing this book.

The eighteen contributors all write from the basis of clinical practice and the majority from a British setting, with only four American contributions. Four of the chapters are concerned with particular lifestages ranging from childhood to old age, and emphasise those aspects of psychological practice the authors consider important. Two chapters are concerned with specific groups: the mentally handicapped and the chronically psychiatrically ill. Four chapters are concerned with very specific conditions: alcohol, drugs, smoking, and obesity. The chapter by Koch on anxiety and depression deals with management of these common conditions, not only in terms of therapy but also the location of services and the need for a preventative approach. The two remaining chapters deal with behavioural marital therapy and behavioural medicine.

This book provides a useful survey of the views of a number of active and experienced clinical psychologists and succeeds in providing an overview of much of the present scene. It inevitably raises questions as to the boundaries between the work of clinical psychologists and psychiatrists, as in places it seems to claim for clinical psychology that which, no doubt, many psychiatrists would see as falling within their own field. There is an emphasis on team work. This is a book that should be available to all psychiatrists and certainly should be included in every psychiatric and clinical psychological library. The print and format is not particularly attractive nor particularly easy to read, and it seems a pity that at this price it could not have been better. Alternatively, perhaps such books should be produced in paperback and therefore more likely to be purchased by individuals rather than mostly by libraries.

A. C. BROWN, *Consultant Senior Lecturer in Mental Health, University of Bristol*

Hypnogogia: The Unique State of Consciousness Between Wakefulness and Sleep. By ANDREAS MAVROMATIS. London: Routledge and Kegan Paul. 1987. 360 pp. £30.00.

This book has made a timely appearance. It examines hypnogogia at a time when there is a renewed interest in cognition and subjective experience within both psychiatry and psychology.

The first part of the book gives a comprehensive historical background to the phenomenon together with numerous descriptive accounts and pictorial illustrations. The second part relates hypnogogia to other states such as dreams, psychic experience, schizophrenia, and creativity. Finally, an attempt is made to determine its brain correlates and function.

According to the author, hypnogogia is a state, often initiated consciously and deliberately but frequently becoming automatic, in which original revelations of a psychic, artistic, or scientific nature may occur. It is usually pleasant and can be therapeutic.

"Hypnogogia" certainly makes fascinating reading to both the layman and those with some knowledge of the field. It also serves as an encouragement to the reader to initiate his own personal investigation of what is essentially a subjective experience.

ALYSON BOND, *Lecturer, Institute of Psychiatry, London*

Functional Psychological Testing: Principles and Instruments. Edited by RAYMOND B. CATTEL and RONALD C. JOHNSON. New York: Raven Press (distribution for Brunner/Mazel). 630 pp. $88.50.

The term 'functional' in the title of this book could mislead readers into expecting its contents to deal with the testing of practical, everyday functioning of human beings. In fact, the editors use the term in its most mathematical sense, the concern of the contributing authors being with exactness of measurement and principles of testing rather than with perhaps more fundamental questions concerning the ecology of testing. One of the editors states that functional psychological testing is 'based on quantitative personality theory', and readers who find this statement comfortable might find the book instructive and useful.

The book is in three sections: 'Psychometric principles in testing', 'Available structured tests for functional psychometry', and 'Art of testing in psychological practice'. These titles themselves are indicative of what I found to be the over-ambitious intentions of the editors, who have produced a book which is unnecessarily complicated. The section on psychometric principles is an example of intellectual overkill, which Anastasi (1982) avoids in her much more succinct coverage of the topic.

While I approve of Cattel's scorn for sloppy science and tests such as the Rorschach, I am not convinced that subjectivity does not enter the text of this book on a number of occasions. I was offended by the value judgements in chapters 8 and 20 on the ending of the Eleven Plus examination in Britain. On page 154, for example, the contributors write: "... in Britain, the labor (*sic*) government's abolition of selection by intelligence test for more advanced education ... was frightful." Statements of this kind – and there were others of similar ideology – should have been rooted out of this book by editors who pride themselves on their pursuit of objectivity.

I liked the historical accounts, particularly on industrial and vocational selection. There is a useful discussion on available attitude scales, and ideas on how to design such a scale. For me, the most interesting chapter was the one dealing with legal considerations for the psychologist. Overall, although I found the book useful on instruments, I found it almost unreadable on principles and kept wondering whether *my* education was at fault. I suspect that this American text will have a similar effect on other British readers who may not be familiar with quantitative personality theory.

BARBARA WILSON, *Senior Lecturer, University Department of Rehabilitation, Southampton*

Sexuality and Medicine. Vol. II: Ethical Viewpoints in Transition. Edited by EARL E. SHELP. Dordrecht, The Netherlands: Kluwer. 1987. 279 pp. Dfl. 130.00, $49.00, £38.95.

This is in the generally excellent *Philosophy and Medicine* series published by Reidel. It is the second of two volumes on aspects of sexuality; these can be read independently, and each is complete in itself.

This volume includes twelve essays by doctors, philosophers, and theologians whose concerns appear generally relevant to clinicians. I found three chapters particularly interesting. In 'An historical comment', John Duffy summarises the major changes in society's attitudes to sexuality since 1800, and notes how negative views which developed as 1900 approached have provided a legacy which remains. A century's presumed determinants and consequences of masturbation are a monument to medical, philosophical, and theological absurdity.

Chapters by R. Baker and N. Grose & E. Shelp include case material discussed in refreshing ways and cogently make the point that values and ethical questions are intrinsic to solving sexual problems. This is true for all helping activities, but is more pointedly so in the sexual field. Such issues should not be ignored, and this book is an interesting and cogent reminder of their importance.

J. P. WATSON, *Professor of Psychiatry, Guy's Hospital, London*

1987 Year Book of Psychiatry and Applied Mental Health. Edited by FREEDMAN, LOURIE, MELZER, NEMIAH, TALBOTT and WEINER. London: Wolfe Medical Publications. 1987. 499 pp. £36.50.

One of the most daunting tasks that faces clinicians is remaining in touch with advances in knowledge over an ever-widening area. The general psychiatrist may be aware of current thinking about the organic substrates of schizophrenia, on which this Year Book reviews many papers, but not perhaps equally aware of the confusing claims for the advantages of recent antidepressants, as well as, perhaps, objective measures of transference. This book is most valuable in addressing this problem, and gathers together summaries of papers from 97 journals.

Each of the 17 chapters is introduced by one of the editors, outlining the main directions of research and placing the articles usefully in a historical perspective. These introductions, and the editorial comments on papers, may be somewhat idiosyncratic and even dogmatic, but nevertheless are stimulating. For example, to state (page 456) that "violence may be as American as apple pie" without levels of probability is refreshing in a learned journal. A few readers will be irritated by the emphasis on American journals, but this, I think, has the advantage of drawing attention to problems which will spread rapidly across the Atlantic. The current American fashion in substance abuse, for example, on which there are a number of papers, is now becoming apparent in Great Britain. Equally, several papers on the plight of the chronic psychiatric patient who is homeless in an urban society should underline our need for caution in the closure of psychiatric facilities for chronic disorders. I found this book useful and easy to consult. It should be in all postgraduate libraries, where it will be useful to psychiatrists and trainees alike.

BERNARD ADAMS, *Consultant Psychiatrist, University College Hospital*

Insanity: the idea and its consequences. By THOMAS SZASZ. New York: John Wiley. 1986. 414 pp. $17.95.

Szasz first burst on the psychiatric scene as one of the stars of the anti-psychiatry movement in 1961 with the publication of *The Myth of Mental Illness*. Perhaps uncertain as to whether his message was clear, Szasz added a one-page summary of the main argument to the British paperback edition of 1972. This précis has always been useful, and students have frequently been referred to it. All praise to Szasz for brevity and clarity.

However, it would appear that Szasz has not been content to neglect the alternative strategy for selling his message: not brevity but prolixity, as book after book extolling the same basic theme has emerged in the past quarter century. The book under consideration here is no exception. "Insanity: the idea" might suggest something different – perhaps an historical look at how the word has changed its meaning and use over time; however, the nearest Szasz gets is to look the word up in a handbook of the history of ideas, and, finding it missing, to suspect another (psychiatric?) plot.

The first claim in Szasz's 1972 summary – and the basis of his work – is that illness can only occur in the body, not in the mind. The argument is rehearsed again here: diseases of the body occur in nature; diseases of the mind, because of their lack of biological correlates, only in metaphor. Szasz, as usual, never doubts that the difference between a physiological bodily process and a pathological bodily process might be other than written in tablets of stone. Because he fails to see that "pathological" as referring to the body is a social construction ("nature" has only variety, it is humans who evaluate), just as it is when referring to the mind, he is only half right. He is also half wrong, and this ultimately spoils a passionate analysis which has its moments of insight. In this case, as with the others, potential readers might first be directed to the yet-to-be beaten one-page summary.

DAVID ARMSTRONG, *Senior Lecturer, Unit of Sociology, United Medical and Dental Schools of Guy's and St Thomas's Hospitals*

Adolescence and Development Breakdown: A Psychoanalytic View. By MOSES LAUFER and M. EGLE LAUFER. New Haven and London: Yale University Press. 1984. 225 pp. £6.95.

This book has now been published in paperback form. It is the result of the authors' experience of treating seriously disturbed adolescents in psychoanalysis. With the help of illustrative clinical material, the authors describe the adolescent's developmental task in integrating sexuality and aggression. They examine the complex pathological solutions adopted when development goes awry, and discuss suitability for analytic treatment and management of acting-out during therapy.

The authors have many important things to say in this book that contribute greatly towards illuminating an area relatively neglected in the psychoanalytic literature. The style of the prose does not make for particularly easy reading, but despite this I am sure that all those who adopt a psychotherapeutic stance in their work with adolescents will find the book extremely helpful and thought-provoking. For them it should be considered to be required reading, and it should be classified as recommended reading for adult psychotherapists.

DENIS V. CARPY, *Consultant Psychotherapist, Adult Department, The Tavistock Clinic*

Helping Delinquents Change: A Treatment Manual of Social Learning Approaches. By JEROME S. STUMPHAUZER. New York: The Haworth Press. 1986. 213 pp. $24.95.

Stumphauzer is Clinical Professor of Psychiatry and the Behavioural Sciences at the University of Southern California School of Medicine. His career has focused on the behavioural treatment of delinquency, and he has published extensively on the subject. The book is not intended to be a highly academic textbook or research review; nevertheless, three key references are provided at the end of each chapter and there is, in addition, a considerable bibliography at the end of the book. It is the reports of follow-up studies that are in short supply, leaving one wondering whether the long-term effectiveness of the approaches used matches the self-evident enthusiasm of the author.

The intention of the author was to produce an easily-read, non-technical guide for practitioners such as counsellors, teachers, and probation officers working with delinquents and using a social learning approach. The book is very successful in meeting its aims, and is easy to read. There are four introductory chapters devoted to understanding delinquent behaviour and social learning theory; the remaining chapters describe particular techniques applicable in different settings, e.g. probation and community programmes, and occupational skills training.

Whether many psychiatrists, especially those working with psychologists who routinely use behavioural methods in their approach to assessment and treatment, would use this book I am uncertain. However, for those with a busy case-load, who work as consultants to "mediators in the natural environment", it could prove to be valuable.

CAROL SHELDRICK, *Consultant in Child and Adolescent Forensic Psychiatry, The Maudsley Hospital*

Caught in Crossfire: Children and the Northern Ireland Conflict. By ED CAIRNS. Belfast: The Appletree Press. 1987. 179 pp. £5.95 (pb), £11.95 (hb).

This is a book about the children of Northern Ireland and how they appear to have been affected by the social and political situation there and by the violence which has been a feature of life in that province in the last decade. A few studies of a clinical kind by psychiatrists and psychologists are mentioned, but the majority of the investigations referred to can best be described as falling into the categories of social psychology and 'scientific' sociology. It would be unfair to reveal what conclusions the author comes to concerning rates of psychiatric disorder, criminality, truancy, and educational handicaps of the children in Northern Ireland; suffice it to say that the book is a good source of this information. A graphic account of the cultural divide is provided, and some of the efforts being made to breach it are mentioned. This is a useful contribution to the study of young people exposed to circumstances of exceptional stress.
